Purified Interleukin-3 and Erythropoietin Support the Terminal Differentiation of Hemopoietic Progenitors in Serum-Free Culture

By Junko Suda, Toshio Suda, Kazuo Kubota, James N. Ihle, Masaki Saito, and Yasusada Miura

We studied the effect of purified interleukin-3 (IL-3) and erythropoietin on colony formation by hemopoietic progenitors in serum-free cultures of spleen cells from 5-fluorouracil (5-FU)-treated mice. In the presence of IL-3 alone, most of the multilineage (three or more lineages) colonies did not contain erythroid cells. However, in the presence of IL-3 and erythropoietin, most of the multilineage colonies contained various numbers of erythroid cells. Replating experiments suggest that IL-3 maintains the growth of the progenitor cells, which could differentiate into erythroid cells. Erythropoietin facilitated the terminal differentiation and amplification of erythroid cells, although it did not sustain the growth of multipotential stem cells. Single-cell transfer experiments demonstrate that IL-3 supported the late stages of differentiation of neutrophils, macrophages, eosinophils, and megakaryocytes in the absence of lineage-specific factors. Therefore, IL-3 supports the differentiation of multilineage hemopoietic progenitors, and the terminal differentiation of most hemopoietic lineages, with the exception of the erythroid lineage.

© 1986 by Grune & Stratton, Inc.

ONE important question in hemopoiesis is how multipotential hemopoietic progenitors develop into the different blood cells. Clonal growth of hemopoietic cells requires hemopoietic factors. Highly purified fractions of WEHI-3–conditioned medium have been shown to support the growth and differentiation of cells of several blood cell lineages.[1,2] The protein for this activity has been purified to apparent homogeneity and was termed interleukin-3 (IL-3).[3] IL-3 has been demonstrated to have mast cell growth factor activity and granulocyte-macrophage colony-stimulating activity.[4] Another hemopoietic factor, human erythropoietin, has been isolated from urine of aplastic anemic patients in a high yield with a simple purification procedure using an immunoabsorbent column of monoclonal antibodies.[5,6]

On the other hand, a highly enriched population of hemopoietic progenitors has been available. Nakahata and Ogawa identified a new class of murine hemopoietic colonies which consist of undifferentiated blast cells that had a high secondary replating efficiency in culture.[7] Subsequently, based on the observation by Bradley and Hodgson,[8] we observed that 5-fluorouracil (5-FU) treatment of mice provided significant enrichment of the progenitors.[9] Recently, we showed that purified IL-3 supported the formation of both blast cell colonies and multilineage colonies.[10]

The in vitro systems used in the above experiments contain substantial amounts of sera which may have erythropoietin and other hemopoietic factors. Guilbert and Iscove initially demonstrated that serum could be replaced by a chemically defined media for the growth of murine hemopoietic progenitors.[11,12] We reported a modification of this method for the growth of granulocyte-macrophage colonies using agar cultures.[13] More recently, the growth of primitive erythroid and nonerythroid progenitors in serum-free medium has been described.[14,15]

We studied the effects of highly purified IL-3 and erythropoietin on the differentiation and proliferation of hemopoietic progenitors in a serum-free methylcellulose culture system. We also examined the role of IL-3 in the terminal differentiation of hemopoietic progenitors in single-cell transfer experiments.

MATERIALS AND METHODS

Cell preparation. Ten- to 15-week-old female BDF$_1$ mice were obtained from the Shizuoka Experimental Animal Center (Shizuoka, Japan). We administered 5-FU (F Hoffmann-La Roche & Co, Ltd Basel, Switzerland) at a dosage of 150 mg/kg of body weight through the tail vein[8,9] Spleen cells were harvested 4 days after the 5-FU injection and single-cell suspensions were prepared from pooled spleens of three mice by washing them three times with Iscove's modified Dulbecco's tissue culture medium (IMDM; GIBCO Laboratories, Grand Island, NY).

Serum-free media. The serum-free media were prepared by a modified version of the method of Iscove et al[11,13] One mL of 1.2% methylcellulose (Fisher Scientific, Norcross, Ga) in IMDM contained 15 mg of bovine serum albumin (BSA; Sigma Chemical, St. Louis, Mo), 600 μg of human transferrin (Sigma Chemical), 160 μg of L-χ-phosphatidylcholine (Sigma Chemical), 96 μg of cholesterol (Wako Pure Chemical Industries, Osaka, Japan), and 400 U of IL-3 in the presence or absence of 2 U of highly purified human urinary erythropoietin (Snow Brand Milk Products Co, Ishibashi, Japan).

BSA was deionized with ion exchange resin AG 501-X8(D) (Bio-Rad Laboratories, Richmond, Calif) according to the method of Tepperman et al[16] and an isotonic solution was made with IMDM BSA used in this study was essentially fatty acid free and globulin free. Before use, 0.1 mL of 7.5% sodium bicarbonate was added to each 2.5 mL of BSA and the pH adjusted to 7.2. Transferrin was fully iron-saturated with FeCl$_3$. Cholesterol and L-α-phosphatidylcholine were dissolved in IMDM according to the method of Iscove et al.[11,12] Before use, 7% sodium bicarbonate was added in the same manner as BSA. IL-3 was purified to homogeneity from WEHI-3–conditioned medium.[3] We used purified IL-3 with a specific activity of 5 × 10^6 U/mg protein. The stock solution contained 40,000 U/mL of activity and was kept frozen in PBS with 1 mg/mL BSA. Erythropoietin purified from human urine using monoclonal antibody technique was generously provided by Dr Masatsugu Ueda in Snow Brand Milk Products Co. It had a specific activity of 81,600 U/mg protein.[5]

Clonal cell culture. Cultures of 1.2 × 10^6/mL spleen cells from 5-FU–treated mice were prepared in 35 mm nontissue culture dishes (Falcon, Oxnard, Calif) of serum-free methylcellulose medium

containing 400 U/mL of IL-3 and/or 2 U/mL of erythropoietin or 10 μg/mL of BSA as a control. Colony growth was observed daily under an inverted microscope. When colonies appeared to have matured, individual colonies were lifted with a 3 μL Eppendorf micropipette and cell number was counted using a hemocytometer. The samples were spun in a cytocentrifuge (Cytospin, Shandon Southern, Sewickley, Pa) and stained with May-Grunwald-Giemsa staining as described previously.[17] In order to confirm lineage, we used specific staining; dual esterase staining for granulocytes and macrophages,[18] toluidine blue staining for mast cells, benzidine staining for erythroid cells, and cholinesterase staining for megakaryocytes.[19]

Replating experiment of blast cell colonies. On day 10 of cultures containing only IL-3, blast cell colonies were picked up from the methylcellulose medium and suspended in 0.1 mL of IMDM. The sample was added with 400 U/mL IL-3 and 2 U/mL erythropoietin in the culture dish. The dish was gently agitated in order to disperse the cells. Cultures of replated cells were then incubated at 37 °C in 5% CO_2.[9] The multilineage colonies were lifted up on day 12 of incubation and examined for cell number and the morphology of the individual colonies.

Single cell transfer experiments. Spleen cells from 5-FU–treated mice were cultured in serum-free methylcellulose medium in the presence of 400 U/mL of IL-3. Blast cell colonies consisting of 50 to 100 cells were picked up as mentioned above on days 10 to 14 of culture. The cells were suspended in 1 mL of serum-free methylcellulose medium containing 400 U/mL of IL-3 in the second 35-mm culture dish. Transfer of a single cell to the third culture dish containing 400 U/mL of IL-3 in 1 mL serum-free methylcellulose medium was performed under direct microscopic visualization using a fine Pasteur pipette with a diameter of approximately 30 μm which was attached to a micromanipulator (Narishige Scientific Instrument Lab, Tokyo, Japan). After confirmation of the presence of a single cell in each dish, incubation was carried out. On 6 to 10 days of incubation, when the colonies appeared to have matured, individual colonies were lifted. Samples were spun in Cytospin and stained with May-Grunwald-Giemsa.[20,21]

RESULTS

Effect of IL-3 and erythropoietin on colony formation. Blast cell colonies and multilineage colonies were formed in the serum-free methylcellulose medium in the presence of purified IL-3. The number of colonies formed in this culture was about half that formed in the serum-containing culture. In the serum-free culture, blast cell colonies appeared later than in the serum-containing culture system.[10] As a control, 10 μg/mL BSA, which was used in the IL-3 stock preparations, did not support the colony formation, nor did erythropoietin support the colony formation.

The numbers and types of colonies supported by IL-3 with or without erythropoietin were compared. On days 14 to 21 of incubation, when the colonies appeared to have matured, individual colonies were lifted from the methylcellulose medium and examined morphologically. Addition of 2 U/mL of highly purified erythropoietin caused a significant change in the appearance of erythroid lineage in the colonies. Fig 1 shows representative multilineage colonies and cytospun preparation of both groups. Table 1 shows the numbers of various types of colonies identified from three dishes. In the presence of IL-3 and erythropoietin, 33 out of 55 colonies were multilineage (three or more lineages) colonies, 31 of which contained erythroid lineage. By contrast, in the presence of IL-3 alone, 29 out of 56 colonies were multilineage, 26 of which did not contain erythroid lineage. The numbers of neutrophil-macrophage colonies and macrophage colonies in both groups were similar. On day 21 of incubation, 9 blast cell colonies were still observed in the dishes containing IL-3 and erythropoietin, and 2 blast cell colonies remained in the dishes containing IL-3 alone. Each blast cell colony consisted of 20 to 100 cells, which showed no sign of differentiation.

There were no significant differences in the percentage of megakaryocyte, eosinophil, neutrophil, macrophage, or blast cell in the multilineage colonies in each dish (Table 2). Fig 2 shows a comparison of percentage of erythroid cells in multilineage colonies in IL-3 plus erythropoietin and IL-3 alone. In the presence of IL-3 and erythropoietin, 31 out of 33 multilineage colonies contained erythroid cells, ranging from 2.0% to 93.6% of the total cells per colony. On the other hand, in the presence of IL-3 alone, only 3 out of 29 multilineage colonies contained erythroid cells which were less than 5% of the total cells per colony. These cells were benzidine positive and some of them denucleated. Although the size of the multilineage colonies varied widely, the cell number in each colony was significantly correlated with the

(D) A megakaryocyte derived from a single progenitor.

blast colonies, which served for single cell transfer. Of a total of 208 single cells, 111 yielded colonies. Of these, 62 colonies were picked up and the morphology examined. There were 56 macrophage colonies, 2 megakaryocyte colonies, 1 eosinophil colony, and 3 neutrophil-macrophage colonies. Fig 3 shows a neutrophil-macrophage colony derived from a single cell in the serum-free culture dish containing IL-3. It also presents the mature neutrophils and a megakaryocyte supported by IL-3.

DISCUSSION

Hodgson and Bradley demonstrated that high concentrations of developmentally early cells were obtained by treating mice with 5-FU.[8] Following the injection of 5-FU, the numbers of erythroid progenitors and granulocyte-macrophage progenitors are markedly reduced. On the contrary, the numbers of multipotential hemopoietic cells are less affected by this treatment.[9] Using spleen cells from 5-FU–treated mice, we have shown that IL-3 supports the blast cell colony formation and multilineage colony formation. In a serum-containing culture system, however, the addition of 2 U/mL of erythropoietin did not cause any significant change in the number of multilineage colonies containing erythroid cells.[10]

In this study, we showed that IL-3 supports the formation of blast cell colonies and multilineage colonies in serum-free cultures. In IL-3 alone, a few multilineage colonies contained a low percentage of erythroid cells. The low frequency of erythroid cells may be due to the ability of IL-3 to support the terminal differentiation of erythroid cells. Alternatively, the bovine serum albumin and human transferrin used in this study might contain a small amount of erythropoietin. However, a significant level of erythropoietin was not detected by a radioimmunoassay. Values in the range of 10 mU/mL are near the lower limit of sensitivity of this assay. Last, cells in multilineage colonies or scattered cells in the culture dish might produce erythropoietin or erythropoietin-like substance(s), but no erythropoietin was detected in the media conditioned by spleen cells. Most recently, Goodman et al reported that IL-3 stimulates the full development of many erythroid burst formations in serum-free cultures without detectable erythropoietin.[23] The cause of the difference is unknown. Contaminants other than erythropoietin in the bovine serum albumin might contribute to the apparent erythropoietin dependence.

In the presence of IL-3 and erythropoietin, most of the multilineage colonies contained erythroid cells. The replating experiments of blast cells from the dishes containing IL-3 to the dishes containing IL-3 and erythropoietin suggest that IL-3 maintains the growth of progenitor cells which could differentiate to erythroid cells. On the other hand, erythropoietin did not support any kind of colony formation of spleen cells from 5-FU–treated mice. From these findings, we concluded that erythropoietin facilitates the terminal differentiation and amplification of erythroid cells. These data provide direct evidence for the model proposed by Iscove on the basis of responsiveness of hemopoietic cells to erythroid burst-promoting activity and erythropoietin.[24] Moreover, it seems to be interesting to examine whether blast cells can differentiate, when they are replated from the dishes containing IL-3 to dishes containing erythropoietin alone. In order to exclude the effect of IL-3 which might have been transferred to the replated culture, enough amounts of neutralizing antibodies to IL-3 would be necessary.

Single cell transfer experiments demonstrated that IL-3 plays a direct role in the differentiation of hemopoietic progenitors without the requirements for interactions with other cells. Without hemopoietic factors directed toward late stages of hemopoietic differentiation, the terminal differentiation of neutrophils, macrophages, eosinophils, and megakaryocytes was supported by IL-3. In summary, IL-3 supports the differentiation of multilineage hemopoietic progenitors, and the terminal differentiation of most hemopoietic lineages with the exception of the erythroid lineage.

ACKNOWLEDGMENT

We would like to thank Dr Masatsugu Ueda for generous provision of purified erythropoietin and the measurement of erythropoietin.

Monoclonal Antibody-Defined Functional Epitopes on the Adhesion-Promoting Glycoprotein Complex (CDw18) of Human Neutrophils

By W.J. Wallis, D.D. Hickstein, B.R. Schwartz, C.H. June, H.D. Ochs, P.G. Beatty, S.J. Klebanoff, and J.M. Harlan

We have evaluated the functional and immunochemical activities of three monoclonal antibodies (MoAbs) minimally reactive with adherence-defective neutrophils (PMN) from a patient with recurrent bacterial infections. In studies with normal PMN, MoAbs OKM1 and 60.1 both precipitate the same 165kd α-subunit (α_M) within an α-β heterodimer complex (CD11). The CD11 complex is part of a larger complex composed of four glycoproteins (CDw18) precipitated by MoAb 60.3, with properties suggesting that the CDw18 complex is equivalent to the Mac-1, LFA-1, p150, 95 glycoprotein family implicated in adherence-dependent leukocyte functions. PMN adherence to endothelium, spreading on surfaces, aggregation, and phagocytosis of zymosan particles were all inhibited in a dose-dependent fashion by MoAb 60.1 (analogous to previous studies with MoAb 60.3) while MoAb OKM1 had no effect. These findings unify previously disparate observations and suggest that a functionally active site on the adherence promoting glycoprotein complexes CD11 and CDw18 is distant from the α_M epitope recognized by MoAb OKM1 but closely associated with the α_M epitope recognized by MoAb 60.1 and the β-epitope (or epitope created by alpha-beta quarternary structure) recognized by MoAb 60.3.

CONSIDERABLE attention has been directed toward a family of structurally related glycoproteins important in adherence-dependent leukocyte functions (reviewed in reference 1). Investigations with monoclonal antibodies (MoAbs) and neutrophils (PMN) have identified three such heterodimers with distinct α-subunits and a common β-subunit. Monoclonal antibodies recognizing antigens originally considered lymphocyte function-associated (also found on PMN) have been designated the LFA-1 series and bind a glycoprotein of M_r 177 kd designated α_L.[2-4] Monoclonal antibody OKM1 recognizes a glycoprotein of M_r 165 kd designated α_M on monocytes, PMN, and natural killer (NK) cells.[5,6] The α_M moiety is also recognized by MoAbs anti-Mo1,[6-8] OKM9,[4,9] and OKM10,[4,9] and appears to be identical to the receptor for complement product C3bi (CR3).[9,10] Reagents have recently been developed that identify the α-subunit (α_X) of a third heterodimer in this family, the p 150, 95 complex (See Note Added in Proof).[4] Additional MoAbs that may bind the common beta-subunit shared by all three heterodimers include MoAbs TS1/18,[2,4] 1B4,[9] and MHM23.[11,12]

Investigation has also been directed toward patients with recurrent bacterial infections whose PMN fail to express the adhesion-promoting molecules and fail to bind (or bind weakly) this family of MoAbs. Neutrophils from these patients are defective in adherence-dependent functions such as spreading, aggregation, chemotaxis, and phagocytosis.[13-19] We have reported two such patients whose PMN are adherence-defective and fail to react with reagents developed within our laboratories, MoAbs 60.1 and 60.3.[17,20] These antibodies are of considerable interest since binding of either to normal PMN induces defects in adherence-dependent functions similar to those observed in patients.[11,17,20,21] Studies with normal PMN have indicated that MoAb 60.1 recognizes a heterodimer with α-subunit similar to α_M (designated the CD11 complex by the Second International Workshop on Human Leukocyte Differentiation Antigens) and MoAb 60.3 precipitates at least three distinct polypeptides (designated the CDw18 complex).[11,22] The relationship between the glycoproteins recognized by MoAbs 60.1 and 60.3 and those identified by the LFA-1 and OKM1 reagents has previously been unclear since varying techniques of immunoprecipitation and gel electrophoresis in different laboratories have produced substantial variability in M_r.

The inhibitory effects of MoAbs 60.1 and 60.3 suggested to us that these reagents bind epitopes within the CD11 and CDw18 complexes centrally important in the adherence process. In this report we describe the results of studies comparing the functional and immunochemical activities of MoAbs 60.1 and OKM1. Our findings indicate that MoAbs 60.1 and OKM1 both immunoprecipitate the α_M subunit, but only MoAb 60.1 inhibits adherence-dependent PMN functions. These observations lend support to a recently proposed model of glycoprotein interaction associated with adherence-dependent leukocyte functions.[1]

MATERIALS AND METHODS

Neutrophils. Whole blood from normal healthy donors or the glycoprotein-deficient patient[17] was obtained by venipuncture and collected in heparin- (5 U/mL; Elkins-Sinn, Inc, Cherry Hill, NJ) coated syringes. Neutrophils were isolated by centrifuging whole blood on Ficoll-Hypaque (Pharmacia Fine Chemical, Piscataway, NJ) cushions, sedimentation of the Ficoll-Hypaque pellets in 3% dextran at room temperature, and lysis of residual red blood cells by hypotonic saline at 4 °C.[23]

Monoclonal antibodies. The preparation of murine monoclonal antibody (MoAb) 60.1 (IgG$_1$ kappa) and MoAb 60.3 (IgG$_{2a}$ kappa) has been described.[11,20] Previous studies indicate that MoAb 60.3 reacts with all human leukocytes and MoAb 60.1 reacts with all PMN, monocytes, some NK cells, and some lymphocytes. Monoclonal antibody OKM1 (murine IgG$_{2b}$; Ortho Diagnostics, Raritan, NJ) reacts with human PMN, monocytes, and NK cells. As previously reported,[20] murine MoAb H11 (IgG$_{2a}$-kappa) reacts with

a 120 kd protein present on all PMN and some T lymphocytes and was used in these studies as a positive control. Murine MoAb 9E8 recognizes a phage membrane glycoprotein and has no specific reactivity with leukocytes or endothelium.[24] Monoclonal antibodies were purified by solid phase absorption on staphylococcal protein A columns (Pharmacia Fine Chemicals, Uppsala, Sweden)[25] and the concentration of purified antibody determined by Bradford assay.[26] In adherence and aggregation assays, both MoAbs 60.1 and OKM1 were prepared in PBS with final 0.02% sodium azide (J.T. Baker Co, Phillipsburg, NJ) and 0.1% bovine serum albumin (BSA; Irvine Scientific Co, Santa Ana, Calif). Earlier studies indicated that this concentration of azide had no effect on normal neutrophil adherence or aggregation. All other studies were conducted with MoAbs in PBS without azide or albumin.

Immunofluorescence flow cytometry. Immunofluorescence flow cytometry was performed using PMN from a normal donor and adherence-defective PMN from a patient (patient 1 in reference 13). Neutrophils were stained within siliconized polypropylene tubes (12 × 75 mm, Falcon, Oxnard, Calif). One million cells were suspended in 1 mL of phosphate buffered saline without calcium or magnesium (PBS−; Grand Island Biologic Co, Grand Island, NY) and washed with Waymouth's 752/1 media (Grand Island Biologic Co) and 5% pooled human plasma. Cells were incubated with saturating concentration of MoAb (40 ug/mL) for 30 minutes on ice, then fixed in freshly made 0.5% paraformaldehyde (Fisher Scientific Co, Pittsburgh, Pa) for 5 minutes, washed twice with 5% heat-inactivated fetal calf serum (FCS; Grand Island Biologic Co), and suspended in 25 uL of a saturating concentration of detecting antibody (fluorescein isothiocyanate (FITC)-rabbit antimouse immunoglobulin; TAGO, Burlingame, Calif) for 30 minutes on ice. Cells were washed once with 5% FCS and again with 1% BSA in PBS−. The final washed cell pellets were suspended in 0.5% paraformaldehyde and stored for up to three days in the dark at 4 °C prior to analysis. Analysis was performed by flow cytometry using a fluorescence-activated cell sorter (FACS 440, Becton Dickinson and Co, Sunnyvale, Calif) with a 50 micron orifice.

Immunoprecipitation and gel electrophoresis. Radioimmunoprecipitation studies were conducted using a previously published technique.[27] Briefly, neutrophils were surface labeled with ^{125}I by the lactoperoxidase method, then disrupted in cell lysis buffer [0.5% nonidet P-40, 0.15 mol/L NaCl, 0.05 mol/L EDTA, 0.05 mol/L Tris-HCl, pH 8.0, and 2 mmol/L phenylmethylsulfonyl fluoride (Sigma Chemical Co, St. Louis, Mo)]. Lysates were cleared of nuclei by centrifugation at 1500 × g for 10 minutes. Free iodide was separated from labeled proteins using Sephadex G-25 (Pharmacia). The amount of trichloroacetic acid (TCA) precipitable ^{125}I was determined for each lysate, and the concentrations of protein radiolabel equalized. Lysates were cleared of nonspecific binding proteins by incubation for 60 minutes with protein A sepharose (Pharmacia) which was then removed by centrifugation. Immunoprecipitation reactions were initiated by addition of 50 ug of MoAb coupled to cyanogen bromide-activated Sepharose 4B (Pharmacia). After incubation at 4 °C for 60 minutes, immune complexes were collected by centrifugation. Radiolabeled proteins were released by addition of sample electrophoresis buffer (62 mmol/L Tris-HCl, 2% SDS, 10% glycerol, 0.02% bromophenol blue with 5% dithiothreitol) and heating to 100 °C for 5 minutes. Immunoprecipitated proteins were separated by electropheresis in 7% polyacrylamide gels in the presence of SDS under reducing conditions. Gels were dried and radiolabeled bands identified by radioautography. In experiments involving a second precipitating MoAb, cell lysates were extensively precleared by the first MoAb until no further radioactivity could be precipitated. The Sepharose-linked precipitating MoAb was then added to the precleared lysate with subsequent analysis as described above.

Spreading of adherent neutrophils on plastic. Normal neutrophils (2 × 10^6 cells/mL, 20 uL cell suspension) in Waymouth's medium in the presence of MoAb or BSA were incubated on plastic coverslips for 45 minutes at 37 °C. Coverslips were pretreated with 100 uL of phorbol myristate acetate (PMA; Sigma Chemical Company) (100 ng/mL in distilled water) and air dried. Coverslips and adherent cells were washed once. Coverslips were fixed with 1% paraformaldehyde and 2% glutaraldehyde in 0.1 mol/L sodium cacodylate buffer pH 7.2, attached to teflon sheets, dehydrated through increasing concentrations of ethyl alcohol, critical point dried using liquid carbon dioxide, then attached to scanning electron microscope stubs using citron paste, coated with a layer of conductive heavy metal, and viewed in a JEOL 35C scanning electron microscope (Tokyo, Japan).

Neutrophil adherence to endothelial monolayers. Human umbilical vein endothelial cells (HUVE) were prepared by collagenase treatment of vessels as previously described.[28] Cells were maintained in RPMI 1640 (Grand Island Biologic Company, Grand Island, NY) with 20% FCS (Hyclone Laboratories, Logan, Utah) and were used in first or second passage only. Individual experiments were performed with HUVE of the same strain and passage number. Endothelial cells were plated in 11 mm wells in 48 well plates (Costar Cluster 3524, Cambridge, Mass) at 5 × 10^4 cells per well and grown to confluence over the course of two or three days. In studies contrasting MoAbs the assays were conducted concurrently with HUVE monolayers prepared from the same strain, passage, and flask. Prior to use in adherence assays, the plates were washed free of media and rinsed twice with Waymouth's medium without serum.

Neutrophils were radiolabeled with ^{51}Cr according to the method of Gallin et al.[29] Purified PMN in Hanks' balanced salt solution without Ca^{++} or Mg^{++} (Grand Island Biologic Company; HBSS−) (2 × 10^7 cells/mL) were incubated with 1 uCi ^{51}Cr per 10^6 cells (sodium chromate, 200 to 500 Ci/g, New England Nuclear, Boston, Mass) at 37 °C for one hour with periodic gentle agitation. Following incubation, the unbound ^{51}Cr was removed in three washes with HBSS. Labeled leukocytes were suspended in Waymouth's medium at a final concentration of 2 × 10^6/mL.

Neutrophil adherence to endothelium was measured by adding 0.25 mL of the purified ^{51}Cr-labeled PMN suspension (5 × 10^5 cells) to each well of the 48 well plate. Neutrophils were preincubated with appropriate concentrations of MoAbs for 30 minutes at 37 °C and added to the endothelial monolayer without prior removal of the unbound antibody. After the addition of leukocytes, control medium, PMA, or calcium ionophore A23187 (Calbiochem-Behring Corp, La Jolla, Calif) was added at the indicated concentration. The culture plates were gently agitated for 1 minute to promote mixing of the PMN suspension with the stimulant and contact with the endothelial monolayers. Plates were incubated for 45 minutes at 37 °C in a 5% CO$_2$ incubator. Medium and unattached cells were aspirated and the plate washed with Waymouth's medium. Aspirated cells and medium were collected in individual counting tubes and the monolayers and attached leukocytes were then lysed overnight with 1N NH$_4$OH. The lysate was aspirated, the plates washed once with lysing solution, and the combined lysate and wash fluid counted in a Beckman gamma spectrometer (Searle Analytic Inc, Division of G.D. Searle and Co, Des Plaines, Ill). Adherence was expressed as percentage of total ^{51}Cr counts remaining attached to the monolayer following incubation:

$$\%\text{ adherence} = \frac{^{51}\text{Cr cpm in lysate}}{\text{Total }^{51}\text{Cr cpm added}} \times 100$$

All samples were run in triplicate or quadruplicate.

Aggregometry. Aggregometry was performed by the nephelometric technique of Craddock et al[30] using a Chrono-log Model 330 platelet aggregometer with Model 702 recorder (Chrono-log Corp, Havertown, Pa). Neutrophils were suspended in HBSS− at a concentration of 2×10^7/mL. Three hundred fifty to four hundred uL aliquots were transferred to silicon-coated cuvettes containing teflon stirring bars. For experiments with MoAbs, PMNs were preincubated with 25 uL of MoAb or BSA for 10 minutes at 37 °C and further incubated for 5 minutes with 25 uL of cytochalasin B (Sigma Chemical Co; 100 ug/mL). The cuvettes containing the preincubated neutrophil suspension were then placed in the aggregometer and stirred at 900 rpm at 37 °C for one minute following the addition of 25 uL of a solution containing 14 mmol/L $CaCl_2$ and 7 mmol/L $MgCl_2$. Fifty uL of HBSS− or PMA in HBSS− (final concentration 100 ng/mL) were added and the resulting changes in light transmission recorded. A one-to-one mixture of neutrophils in HBSS− was used as the cell-poor calibration standard. Quantitation was achieved by measuring the area under the curve using a Hewlett Packard Model 9830A calculator and Model 9864A digitizer. Aliquots of PMN suspension were also removed at various time points for examination by phase contrast microscopy.

Neutrophil phagocytosis. Iodination by PMN was employed as an indirect measure of phagocytosis.[20] Into 12 × 75 mm polyethylene tubes was added 4×10^{-3} mol/L sodium phosphate buffer pH 7.4, 0.128 mol/L NaCl, 1.2×10^{-2} mol/L KCl, 10^{-3} mol/L $CaCl_2$, 2×10^{-3} mol/L $MgCl_2$, 8×10^{-6} mol/L NaI (4 mmol; 0.05 uCi ^{125}I), 2×10^{-3} mol/L glucose, 2.5×10^6 PMN, 0.5 mg opsonized zymosan, 0.25 mg BSA, and the MoAbs at the concentrations indicated, in a final volume of 0.5 mL. The zymosan (ICN Pharmaceuticals, Cleveland, Ohio) was suspended in water at a concentration of 10 mg/mL by homogenization at 4 °C, opsonized by incubation with an equal volume of pooled human serum for 20 minutes at 37 °C, washed, suspended, and then diluted ten-fold in the reaction mixture. The tubes were incubated for 20 minutes at 37 °C in a shaking water bath. The reaction was stopped by the addition of 1 mL of cold 10% TCA, the precipitate collected by centrifugation at 2,500 G for 5 minutes, and washed four times with 2 mL of 10% TCA. The tube containing the precipitate was assayed for radioactivity by gamma spectrometer (Packard). A blank containing the standard salt solution, iodide, and albumin was run with each experiment and the results subtracted from each experimental value. Less than 0.5% of the total added radioactivity was TCA-precipitable in the blank. A standard containing the total amount of ^{125}I in the reaction mixture was counted and the percent iodination was determined as follows:

$$\frac{\text{cpm experimental} - \text{cpm blank}}{\text{cpm standard}} \times 100$$

Results are expressed as the mean nmol of iodide converted to a TCA-precipitable form per 10^7PMN per hour. The results in each experiment were the average of duplicate determinations.

RESULTS

Immunofluorescence flow cytometry. Studies with neutrophils from a normal donor revealed low magnitude nonspecific binding of the negative control MoAb 9E8 and highly significant binding by MoAbs 60.1 and OKM1, which was comparable to that observed with the positive control MoAb H11 (Fig 1A). In contrast, neutrophils from a patient with recurrent infections and adherence-defective phagocytes demonstrated greatly decreased binding of both MoAbs OKM1 and MoAb 60.1 (Fig 1B). Binding of positive H11 and negative (9E8) control MoAbs to the adherence-defective PMN was identical to that observed with normal PMN.

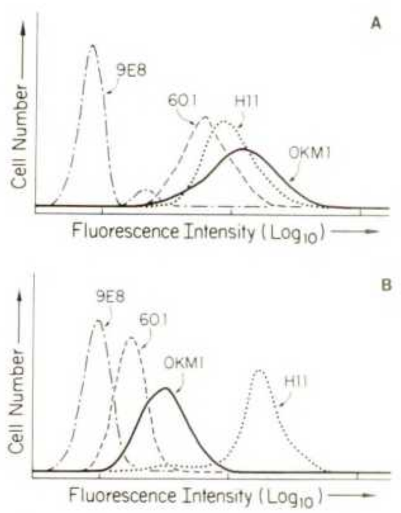

Fig 1. **Monoclonal antibody binding to normal neutrophils (A) and a patient's adherence-defective neutrophils (B). MoAb OKM1 binds a PMN heterodimer of M, 165 kd and 95 kd. MoAb 60.1 binds a PMN heterodimer of M, 165 kd and 95 kd. MoAb H11 reacts with a 120 kd protein present on all PMN and some T lymphocytes. MoAb 9E8 reacts with a phage glycoprotein and has no reactivity with leukocytes. The binding of MoAb OKM1, MoAb 60.1, and MoAb H11 positive control are compared with MoAb 9E8. Binding of MoAbs OKM1, 60.1, and H11 are significant in normal neutrophils. Patient neutrophils fail to bind significantly both OKM1 and 60.1.**

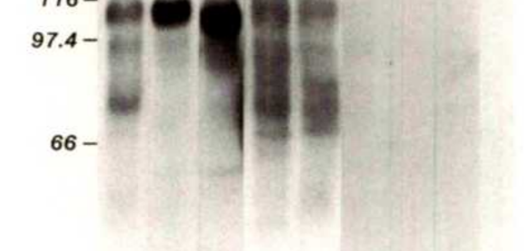

Fig 2. **Immunoprecipitations from ^{125}I-labeled human PMN. Neutrophil lysates were incubated only with precipitating MoAb (lanes 1, 2, and 3) or incubated first with the designated preclearing MoAb, then exposed to the precipitating MoAb. All immunoprecipitates were subjected to 7% SDS-PAGE and autoradiography. Molecular weight markers shown on the left are listed as kd. Preclearance studies with control MoAb 60.5, which is directed to a Class I HLA-framework antigen present on all peripheral blood leukocytes,[11] yielded results identical to those obtained when PMN lysates were preincubated with buffer alone (data not shown).**

Immunoprecipitation and gel electrophoresis. Immune precipitation and SDS-PAGE of ^{125}I surface-labeled neutrophils demonstrated that MoAbs OKM1 and 60.1 precipitated identical heterodimers consisting of an α-subunit of approximately 165 kd (α_M) and a β-subunit of approximately 110 kd (Fig 2). MoAb 60.3 precipitated the same α-chain (α_M) and β-chain as observed with 60.1 and OKM1, along with two additional molecules with approximate molecular weights of 177 kd (α_L) and 150 kd (α_X).

Preclearance of the PMN lysates with MoAb 60.1 or OKM1 removed only the 165 kd molecule from the complex precipitated by MoAb 60.3 (lanes 4 and 5). Preclearance with MoAb 60.1 removed the OKM1 heterodimer and preclearance with OKM1 removed the 60.1 heterodimer (lanes 6 and 7). Preclearance with MoAb 60.3 removed all of the subunits precipitated by 60.1 and OKM1 (lanes 8 and 9). Preclearance studies with control MoAb 60.5, which is directed to a Class I HLA-framework antigen present on all peripheral blood leukocytes,[11] yielded results identical to those obtained when PMN lysates were preincubated with buffer alone (data not shown).

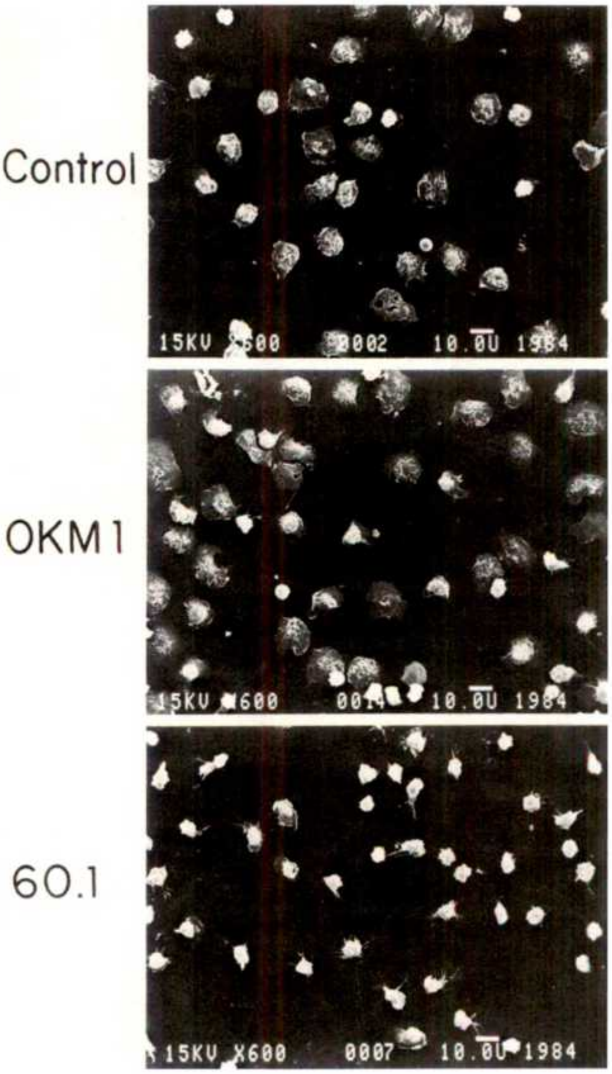

Fig 3. Scanning electron micrographs of PMA-activated neutrophils adherent and spread on polystyrene coverslips. Following a 15-minute incubation with MoAb (40 ug/mL) or BSA (40 ug/mL), neutrophils were incubated on PMA-coated plastic for 45 minutes at 37 °C. Only MoAb 60.1 inhibited PMN spreading.

Effect of MoAbs on spreading of stimulated neutrophils. Neutrophils from normal donors treated with phorbol ester adhered and spread on polystyrene (tissue culture plastic) coverslips. This process was not affected by saturating concentrations of MoAb OKM1 (Fig 3). In marked contrast, normal PMN treated with MoAb 60.1 adhered minimally and failed to spread. PMN assayed in the presence of MoAb 60.1 simulated cells from patients with adherence-defective PMN.[17]

Neutrophil adherence to endothelium. Basal (unstimulated) adherence of ^{51}Cr-labeled PMN in serum-free medium on HUVE monolayers was of low magnitude (11% ± 4%). The addition of PMA to the adherence assay (final concentration 100 ng/mL) markedly augmented neutrophil adherence (88% ± 7%), as did the addition of calcium ionophore A23187 (44% ± 6%). Neutrophil adherence stimulated by PMA or A23187 was not significantly inhibited by coincubation with MoAb OKM1 or BSA. In marked contrast, the augmentation of neutrophil adherence by either PMA or A23187 was significantly inhibited in a dose-dependent fashion by MoAb 60.1 (Fig 4).

Neutrophil aggregation. Neutrophils from normal donors aggregated in response to phorbol ester. Addition of BSA or MoAb OKM1 did not significantly modify PMA-induced aggregation. In contrast, PMA induced minimal aggregation of neutrophils treated with saturating concentrations of MoAb 60.1. Neutrophils incubated with MoAb 60.1 simulated the responses of adherence-defective leukocytes (Fig 5).

Phagocytosis. Figure 6 demonstrates the effect of MoAb 60.1 and OKM1 on iodination by normal PMN. No significant inhibition of iodination was produced by 40 ug/mL of OKM1 under conditions in which MoAb 60.1 was markedly inhibitory, with half-maximum inhibition occurring at a concentration of < 1 ug/mL. The close correlation between the effects of MoAbs 60.1 and 60.3 on iodination and on phagocytosis when the particulate stimulus zymosan was employed[20] and the absence of an effect of MoAb 60.3 on iodination when the soluble stimulus PMA was used[17] suggests that iodination is a measure of the phagocytosis of zymosan under the conditions used here.

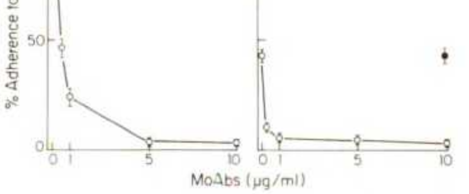

Fig 4. Dose-dependent inhibition of stimulated PMN adherence to cultured vascular endothelium by MoAb 60.1 (open circle). MoAb OKM1 (solid circle) had no apparent effect on stimulated PMN adherence. (A) PMA (100 ng/mL); (B) A23187 (10 umol/L).

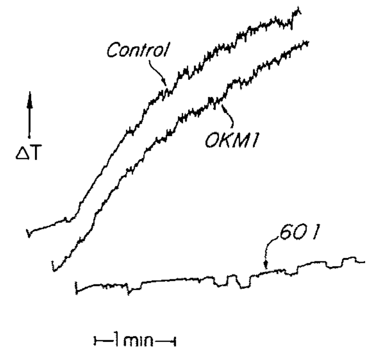

Fig 5. Inhibition of PMA-induced PMN aggregation by MoAb 60.1 (40 ug/mL) and the lack of inhibition by MoAb OKM1 (40 ug/mL).

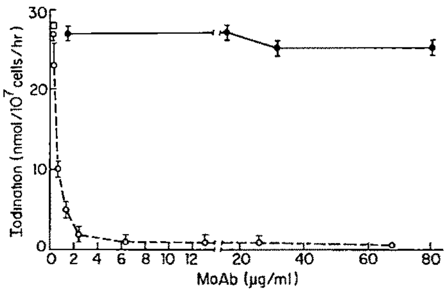

Fig 6. MoAb 60.1 induces a dose-dependent inhibition of PMN phagocytosis of opsonized zymosan as assayed by iodination. MoAb OKM1 is without significant effect.

DISCUSSION

In this report we describe the results of studies comparing the functional and immunochemical activities of MoAbs 60.1 and OKM1. Both reagents demonstrated little reactivity with adherence-defective PMN from a patient with recurrent bacterial infections. This observation confirms previous studies[19,20] and indicates that the epitopes bound by these reagents were either absent or expressed at insignificant levels in patient cells. Immunochemical studies with normal PMN established that both MoAbs bind the same alpha subunit glycoprotein (α_M) within the α-β heterodimer complex (CD11) and that this molecule is part of a larger complex composed of four glycoproteins (CDw18) immunoprecipitated by MoAb 60.3. Assays of adherence-dependent PMN functions were conducted in the presence of MoAbs OKM1 and 60.1. PMN adherence to endothelium, spreading, aggregation, and phagocytosis were all inhibited in a dose-dependent fashion by MoAb 60.1, while MoAb OKM1 had no effect. Thus, only MoAb 60.1 binds a site on the α_M molecule which is critical to the adhesion process.

Glycoprotein deficiency in adherence-defective PMN has previously been defined by minimal reactivity with a variety of murine MoAbs (reviewed in reference 1) and by near absence of selected glycoproteins on electrophoretic analysis of PMN lysates. Missing glycoproteins have been variably reported as 110kd,[15] 180kd,[18,31,32] 150kd,[14,17,21] and 138kd.[19] Many investigators feel that different patients with similar clinical manifestations probably share the same glycoprotein deficiency, and variations in reported molecular weights probably reflect different gel conditions in different laboratories.[1] Recent evidence suggests that adherence-defective PMN fail to synthesize the β-subunit that is necessary for leukocyte surface expression of the α_L, α_M, and α_X subunits.[33] It has been proposed that inheritance of this biochemical and clinical defect is either autosomal recessive[33] or X-linked recessive.[15]

Monoclonal antibodies indirectly map the functionally active site in the adhesion-promoting glycoprotein complex (reviewed in reference 1). We have previously reported that MoAb 60.3 inhibits PMN adherence to endothelium, PMN spreading, phagocytosis of C3bi-opsonized particles, aggregation, and chemotaxis.[11,17,20,21] In this report we have demonstrated that MoAb 60.3 precipitates four molecules with M_r compatible with the α_L, α_M, α_X, and β-chains. This observation suggests that the CDw18 complex is equivalent to the Mac-1, LFA-1, p150, 95 glycoprotein family. Monoclonal antibody 60.3 removed the α_M molecules recognized by 60.1 or OKM1, but MoAbs 60.1 and OKM1 removed only the α_M molecule from the complex recognized by 60.3. Monoclonal antibody 60.3, like MoAbs TS1/18,[4] MHM23,[12] and 1B4,[9] may bind a site on the common β-subunit.[22] Indirect support for this interpretation is found in the observation that MoAb 60.3 binds leukocytes of both myeloid and lymphoid lineages (all expressing β-subunits). Although we cannot rule out the possibility of a cross-reacting epitope on all four subunits, we feel it more likely that the epitope recognized by MoAb 60.3 resides on the common β-subunit. Alternatively, the epitope recognized by MoAb 60.3 may result from the quarternary structure arising from noncovalent association of α- and β-subunits. Supporting this latter interpretation, MoAb 60.3 (like MoAb 1B4[9]) fails to bind to its precipitated polypeptides in their dissociated state (data not shown). Other workers have shown that MoAb anti-Mo1 precipitates the α_M glycoprotein and blocks adherence, spreading, aggregation, and phagocytosis.[34,35] Inhibition of adherence-dependent functions by MoAbs 60.1, 60.3, and anti-Mo1 (but not OKM1) implies that a functionally active site is distant from the epitope recognized by MoAb OKM1 but closely associated with the α_M epitopes recognized by MoAbs 60.1 and anti-Mo1 and the β-epitope (or β-α quarternary epitope) recognized by MoAb 60.3.

The function of adhesion-promoting glycoproteins and the mechanism by which MoAbs inhibit adherence-dependent functions is currently unclear. Previous studies have shown that PMN stimulation with agents such as phorbol ester or calcium ionophore augments PMN adherence to surfaces and simultaneously increases surface expression of epitopes reactive with MoAbs, Mo1, LFA-1, and 60.3.[21,34,36] This results in part from surface recruitment of additional glycoproteins from cytoplasmic granules.[36] PMN-stimulating agents may perhaps further augment adherence by inducing a qualitative change in surface glycoproteins (eg, phosphorylation or proteolytic cleavage) that renders these molecules more intrinsically adhesive, or promotes interaction of glycoproteins with cellular structures (eg, cytoskeleton) involved in adherence phenomena. We presume that MoAb inhibition of adherence-dependent PMN functions results from direct binding or steric hindrance at a functionally important site on the α_M molecule. The results we have presented, however, do not rule out the possibility that MoAb 60.1 inhibition is caused by capping of α_M molecules or by linkage of the α_M moiety with Fc receptors. Inhibition of PMN adherence is unlikely to reflect nonspecific interaction of MoAb with the cell surface membrane since other MoAbs reactive with the PMN surface do not inhibit adherence-dependent functions.[1,11,20,21]

Previous studies with C3bi-coated erythrocytes have demonstrated that adherence-defective PMN from patients with recurrent infections also lack C3bi receptors (CR3).[16,19,20] The 165kd membrane glycoprotein designated α_M appears to be closely associated with or identical to CR3. Antibody blocking studies with normal PMN or monocytes have shown that CR3 function is retained in the presence of OKM1, OKM9, 1B4, and TS1/18,[9] and specifically blocked by MoAbs 60.1, 60.3, anti-Mo1, anti-Mac-1, and OKM10.[9,10,20] Since MoAbs 60.1, 60.3, and anti-Mo1 all block adherence-dependent PMN functions (and OKM1 does not), these data suggest that epitopes mediating CR3 function and epitopes mediating adherence-dependent functions are either in close spatial linkage or identical.

NOTE ADDED IN PROOF

Reagents that identify the α-subunit (α_X) of the p 150, 95 heterodimer have recently been described in the following: Lanier LL, Arnaout MA, Schwarting R, Warner NL, Ross GD: p 190/95, third member of the LFA-1/CR$_3$ polypeptide family identified by anti-Leu M5 monoclonal antibody. Eur J Immunol 15:713, 1985, and Springer TA, Miller LJ, Anderson DC: p 150, 95, the third member of the Mac-1, LFA-1 human leukocyte adhesion glycoprotein family. J Immunol 136:240, 1986

ACKNOWLEDGMENT

We thank Dr Michael Reidy for preparing scanning electron micrographs, Penny Thompson, Kathe Stanness, and Ann Waltersdorph for excellent technical assistance, and Lou Limtiaco for skillful word processing.

Development of a Radioimmunoassay for the Fibrinogen-Derived Peptide Bβ1-42

By Jeffrey I. Weitz, James A. Koehn, Robert E. Canfield, Sharon L. Landman, and Robert Friedman

The peptide Bβ1-42 is the initial cleavage product of plasmin-mediated proteolysis of the NH$_2$-terminal region of fibrinogen or fibrin I, while β15-42 is the major fragment released by plasmin degradation of fibrin II. Numerous studies have described the measurement of plasma Bβ1-42 levels as an index of plasmin activity. Previous assays were indirect and included quantitation of thrombin-increasable fibrinopeptide B immunoreactivity (TIFPB) or measurement of β15-42 with an antiserum (132) which cross-reacted with Bβ1-42. We report on a new antiserum (R142) directed against Bβ1-42 which does not cross-react with β15-42 or fibrinopeptide B. Employing this antiserum, a specific assay for Bβ1-42 was developed. This assay was used to measure plasmin-mediated Bβ1-42 release from fibrinogen and its subsequent proteolysis by thrombin. The selectivity constant (Kcat/Km) for thrombin cleavage of the Bβ14-15 bond of Bβ1-42 was 10^5-fold less than that for proteolysis of the same bond in the intact fibrinogen molecule, thus explaining the stability of this peptide in the presence of thrombin activity in the blood. Similarly, the selectivity constant for plasmin cleavage of the Bβ21-22 bond of Bβ1-42 was 140-fold less than that for proteolysis of the Bβ42-43 bond of fibrinogen, indicating that secondary plasmin attack of the Bβ1-42 molecule is not physiologically important. The specific Bβ1-42 assay provided excellent recovery of peptide added to blood or plasma. Comparison of Bβ1-42 levels with TIFPB values in 37 patient samples yielded good correlation over a wide range of levels ($r^2 = 0.91$). The median plasma Bβ1-42 level in 15 normal individuals was 1.2 pmol/mL. This is similar to the previously reported normal range for TIFPB (1 to 4 pmol/mL) but is higher than the normal level of 0.4 pmol/mL reported with the assay employing antiserum 132. This discrepancy reflects rapid removal of Arg (Bβ42) by plasma carboxypeptidase activity resulting in 50% loss of Bβ1-42 immunoreactivity with antiserum 132 but no loss with R142. To circumvent this problem, we have developed a β15-42 antiserum (R154) which, like antiserum 132, cross-reacts with Bβ1-42. However, Bβ1-42/β15-42 immunoreactivity with R154 is stable in the presence of carboxypeptidase activity. Thus, these studies confirm the utility of measurement of plasma Bβ1-42 as an index of plasmin activity. Further, in vitro studies of Bβ1-42 generation by recombinant tissue-plasminogen activator suggest that radioimmunoassays for the plasmin-derived fibrinopeptides may provide a method for investigating the fibrin(ogen)olytic activity of thrombolytic agents.

© 1986 by Grune & Stratton, Inc.

THE balance between thrombin and plasmin action on fibrinogen has been postulated to be an important determinant of thrombosis.[1] Specific and quantitative analysis of this balance can be assessed by measurement of the products of this proteolysis. Thrombin acts on fibrinogen in a two-step fashion.[2] The first step releases fibrinopeptide A (Aα1–16) from the NH$_2$-terminal region of the Aα-chain producing an intermediate known as fibrin I, while the second step involves cleavage at the NH$_2$-terminal region of the Bβ-chain, releasing fibrinopeptide B (Bβ1–14) and producing fibrin II. In the initial digestion of fibrinogen by plasmin, large segments of the COOH-terminal Aα-chain and Bβ1-42, from the NH$_2$-terminal region of the Bβ-chain, are cleaved and fragment X is formed.[3-6] Fibrin II forms more compact fibers with greater tensile strength than fibrin I,[7] and because it forms α-polymer cross-links, is less susceptible to lysis by plasmin than fragment X.[8] It has been hypothesized, therefore, that the amount of fibrin II formed is an important determinant of thrombosis and that the balance between fibrin II and fragment X formation determines the pathophysiologic consequences of fibrin I generation.[1]

Unlike the Aα and γ-chains, the NH$_2$-terminal region of the Bβ-chain of fibrinogen contains cleavage sites for both thrombin (Bβ14-15 bond) and plasmin (Bβ42-43 bond). The measurement of the products released by these cleavages, fibrinopeptide B and Bβ1-42, respectively, reflects the balance between thrombin and plasmin action on fibrin I. Methods to detect circulating levels of fibrinopeptide B have been described,[9,10] but to date only indirect methods to measure Bβ1-42 have been available.[11,12]

In this study, several β-chain fragments from the NH$_2$-terminal region of human fibrinogen were purified. The peptides Bβ1-42 and β15-42 were selected as immunogens because they are most characteristic of the plasmin-derived fragments from this region. Each peptide was coupled to bovine serum albumin by carbonyldiimidazole, and polyclonal antibodies were produced in rabbits. These antisera were then characterized using radioimmunoassay techniques and their specificity explored using a panel of purified human β-chain fragments. Radioimmunoassays employing these antisera provide useful tools for in vitro and in vivo study of plasmin-mediated proteolysis of fibrinogen and fibrin.

MATERIALS AND METHODS

Preparation of Fibrinogen and Plasmin

Human fibrinogen (Grade L, Kabi, Sweden) was purified as previously described.[13] Plasminogen was prepared from fresh frozen plasma by affinity chromatography, further purified by ion-exchange chromatography, and activated with insolubilized urokinase as described previously.[13]

Purification of Immunogens

N-DSK was prepared by digesting human fibrinogen (Grade L, Kabi) with cyanogen bromide followed by gel filtration over a G-100

From the Department of Medicine, Columbia University, College of Physicians and Surgeons, New York, NY 10032

Supported in part by a research grant from the National Institutes of Health (HL-15486) and by a research fellowship (JW) from the New York Heart Association.

(Pharmacia Fine Chemicals, Uppsala, Sweden) column (4.0 × 200 cm) as described previously.[14] The N-DSK was dissolved in Tris-buffered saline (0.05 mol/L Tris, 0.1 mol/L NaCl, pH 8.6) to a concentration of 20 mg/mL, and digested with 0 01 CU human plasmin/mg N-DSK for 2 hours at 37 °C. The reaction was stopped by the addition of acetic acid (final concentration 10%) and the digest was gel filtered over a Sephadex G-50 superfine (Pharmacia) column (2 5 × 150 cm) in 10% acetic acid. The region containing Bβ1-42 was identified using high performance liquid chromatography (HPLC) and its composition confirmed by amino acid analysis. The Bβ1-42 pool was lyophilized and further purified using semipreparative high performance liquid chromatography, as described elsewhere.[15]

Purification of β-chain Fragments

Bβ1-118 was prepared as previously described.[13] β22-42 was obtained by exhaustive plasmin proteolysis of purified Bβ1-42. The Bβ1-42 was dissolved in Tris-buffered saline, pH 7.4, and digested with human plasmin (1 CU plasmin/mg Bβ1-42) for 3 hours at 37 °C. The reaction was stopped by the addition of phosphoric acid (final pH <4) and the products were separated by HPLC.

β15-42 was prepared by digesting purified Bβ1-42 with human thrombin. Bβ1-42 in Tris-buffered saline, pH 7 4, was incubated with human thrombin (NIH Lot H-1, 60 U/mg Bβ1-42) for 60 minutes at 37 °C. Fibrinopeptide B (FPB) and β15-42 were then separated and further purified by HPLC as previously described.[16] β12-19 and β12-42 were prepared from chymotryptic digests of Bβ1-42. The Bβ1-42 dissolved in Tris-buffered saline, pH 7.4, was digested with chymotrypsin (Worthington Biochemical Corp, Freehold, NJ) using an enzyme to substrate ratio of 1:100 (by weight). After 5 minutes' digestion at 37 °C, phosphoric acid was added to half the reaction mixture (final pH <4) and the products were separated by HPLC. The remainder of the sample was digested for 60 minutes at 37 °C, phosphoric acid was added to stop the reaction, and HPLC was used to separate the products Amino acid analysis demonstrated that the major fragments produced by limited digestion were Bβ1-11 and β12-42, while those produced by exhaustive digestion were Bβ1-11, β12-19, and β20-42.

High Performance Liquid Chromatography (HPLC)

Analytical and semipreparative HPLC were performed using a Waters Associates liquid chromatograph equipped with a Model 660 solvent programmer, two Model 6000A solvent delivery systems, a Waters automatic injector Model 710A, and a Waters data module. Peptides were monitored using a Model 450 variable wave length absorbance detector set at 220 nm. The column employed for all analyses was a μ-Bondapak C_{18} (3 9 mm i.d. × 30 cm) from Waters Associates, which was maintained at 37 °C using a water bath and thermal jacket. Peptide samples were eluted from the μ-C_{18} column either isocratically or using gradients containing various concentrations of acetonitrile in the mobile phase. Buffers used in the chromatography included 0.1% phosphoric acid (HPLC grade, Fisher Scientific Co, Fairlawn, NJ), pH 2.1 (buffer A), and 0.1% phosphoric acid containing 50% acetonitrile, pH 2.1 (buffer B). Milligram quantities of Bβ1-42 and β15-42 were purified using a larger, semipreparative μ-Bondapack C_{18} column (7.8 mm i.d. × 30 cm) also from Waters Associates. The peptides were eluted with acetonitrile gradients produced by a buffer system prepared with 0.1% Trifluoroacetic acid (Pierce Chemical Co, Rockford, Ill), pH 2.1 (buffer A), and 0.1% Trifluoroacetic acid containing 50% acetonitrile, pH 2.1 (buffer B) and were detected at 230 nm. All buffers were prefiltered through a preparative μ-Bondapak C_{18} Porasil B column (7.8 mm i.d. × 61 cm) from Waters Associates and degassed prior to use.

Amino Acid Analysis

Fractions to be analyzed were hydrolyzed in 6N HCl in vacuo for 24 hours at 110 °C and analyzed using standard techniques on a Beckman Model 121 MB amino acid analyzer.[17]

Immunization

Purified Bβ1-42 and β15-42 were conjugated to 2 × crystallized bovine serum albumin (Sigma Chemical Co, St. Louis, Mo) using N-N'-carbonyldiimidazole (Pierce). In a 5 mL reaction vial, 3 mg of each peptide was suspended in 3 mL of anhydrous dimethylformamide (Pierce) containing 10 mg carbonyldiimidazole and the mixture was bubbled with nitrogen for 15 minutes. Five mg of BSA was added and the reaction was continued with stirring and nitrogen bubbling for 30 minutes at 23 °C. The reaction mixture was then desalted on a Sephadex G-25 (Pharmacia) column (2.5 × 40 cm) in 10% acetic acid and lyophilized. The immunogens were resuspended in phosphate buffered saline (0.9% NaCl containing 0.01 mol/L phosphate, pH 7.4) to a concentration of 2 mg/mL and vortexed thoroughly with 3 parts Freund's Complete Adjuvant (Calbiochem-Behring Corp, La Jolla, Calif) until a thick emulsion formed.

White male New Zealand rabbits were immunized with 200 μg of the conjugated peptide using the multiple intradermal injection technique.[18] Ten weeks after the primary injection, each rabbit was boosted with 100 μg of the immunogen given intramuscularly into the haunches. Blood was collected at 8 weeks and every 2 weeks thereafter. To detect an immune response, Bβ1-42 and β15-42 were radioiodinated at residue Bβ41 (tyrosine) with ^{125}I (Amersham Corp, Arlington Heights, Ill) to a specific activity of 30–50 μCi/μg by the chloramine-T method,[19] and specific binding of these tracers was determined.

Radioimmunoassays

TIFPB, fibrinopeptide A (FPA), and fibrinopeptide B were assayed as previously described.[9,11,20] For assay of Bβ1-42 or β15-42, dilutions of standard, test samples, antiserum, and tracer were made in 0.01 mol/L phosphate buffered saline, pH 7.4, with 1% (v/v) normal rabbit serum, 0.1 mg/mL lysozyme (Worthington), and 350 KI units/mL aprotinin (Mobay Chemical Corp, New York, NY) Each assay tube contained 650 μL final volume consisting of the following, in order of addition· 500 μL of standard concentration of peptide to be measured or a dilution of test sample, 100 μL of antiserum (sufficient to bind 25% to 35% of the total bindable counts), and 50 μL of tracer (about 10,000 cpm). After 24 hours incubation at 4 °C, tracer bound to antibody was separated by a second antibody technique. Sheep antirabbit IgG, in quantities capable of binding all of the rabbit IgG, and diluted in 0.01 mol/L phosphate-buffered saline, pH 7 4, supplemented with 20 mg/mL polyethylene glycol 6,000 (Fisher Scientific Co, Springfield, NJ) was added. The tubes were then incubated for 30 minutes at 23 °C, diluted with 2 mL of 0.9% NaCl, and centrifuged at 4,000 g for 20 minutes at 4 °C. The supernatant fluid was aspirated and the pellet was counted for 1 minute on a Rackgamma counter (#1270, LKB Instruments, Rockville, Md).

Kinetic Studies

Because of the specificity of the Bβ1-42 antiserum (see below), kinetic data describing plasmin-mediated cleavage of the Bβ42-43 bond of fibrinogen and subsequent thrombin proteolysis of the Bβ14-15 bond of Bβ1-42 could then be estimated. Fibrinogen (0 1 to 12 μmol/L) was digested with plasmin (01 CU/mL) at 37 °C and the initial velocity of Bβ1-42 cleavage calculated using appearance of Bβ1-42 immunoreactivity during the first 5 minutes of the reaction Less than 10% of total substrate was digested during this time. Purified Bβ1-42 (1.0 to 100 μmol/L) was then digested with thrombin (1.0 U/mL) at 37 °C and initial velocity calculated by measuring disappearance of Bβ1-42 immunoreactivity during the first 5 minutes of the reaction. Again, less than 10% of the substrate had been consumed during this time.

Blood Collection and Processing

Blood from normal individuals was donated by laboratory personnel and house officers who were in apparent good health. Samples were collected from an antecubital vein using a 21-gauge butterfly needle. For Bβ1-42 and TIFPB measurements, 4.5 mL blood was collected into a plastic tube containing 0.5 ml of anticoagulant solution consisting of 1,000 U/ml Trasylol, 1,400 U/ml heparin, 0.01 mol/L adenosine, and 0.02 mol/L theophylline in HEPES-buffered saline, pH 7.4. For in vitro recovery experiments, blood was collected into a plastic syringe and transferred into a plastic tube containing 1/10 the volume of above anticoagulant solution, immediately transferred to a 50 mL conical plastic tube, kept on ice, and mixed gently. The anticoagulated blood was either transferred into 15 × 90 mm polystyrene tubes containing different concentrations of Bβ1-42, mixed gently, and then centrifuged at 1,700 g at 4 °C for 20 minutes, and the plasma pipetted off, or the blood was centrifuged as above and the plasma was then transferred into 15 × 90 mm polystyrene tubes containing different concentrations of Bβ1-42 and mixed gently. In each case, within 30 minutes of blood collection, 2 mL plasma was precipitated with an equal volume of denatured ethanol (Fisher) to remove the fibrinogen, evaporated to dryness, and reconstituted with distilled water as previously described.[11] For in vitro studies of Bβ1-42 generation by recombinant tissue-plasminogen activator (rt-PA), venous blood from normal volunteers was obtained in plastic syringes containing 3.8% trisodium citrate (9:1 v/v) Samples were centrifuged at 1,700 g for 20 minutes at 4 °C and the plasma pipetted off and immediately used for the experiments (see below).

Comparison of Bβ1-42 and TIFPB Assays

Thirty-seven stored ethanol supernatants taken from patients with various clinical disorders were thawed and assayed for Bβ1-42 (using antiserum R142) and for TIFPB. The coefficient of covariance was calculated as described by Sokal and Rohlf[21]

Studies of Stability of Bβ1-42 in Plasma

Incubation of Bβ1-42 in Plasma. Bβ1-42 (30 pmol/mL) was incubated with human plasma at 23 °C for one hour. Aliquots were removed at intervals and the plasma was precipitated with ethanol (50% final concentration), the ethanol evaporated, and the precipitate dissolved in distilled water as previously described.[11] The reconstituted samples were then assayed for Bβ1-42 immunoreactivity using antisera R142, R154, and 132 (a gift of Dr B. Kudryk, New York Blood Center).

Effect of Carboxypeptidase B on the Immunoreactivity of Bβ1-42 in Buffer Solution Bβ1-42 at a final concentration of 20 pmol/mL was incubated at 37 °C in 0.15 mol/L Tris-buffered saline (0.1 mol/L NaCl and .05 mol/L Tris, pH 7.4) with and without porcine pancreas carboxypeptidase B (Worthington). The enzyme activity was determined immediately before use by measuring hydrolysis of hippuryl-L-lysine (Sigma). Final carboxypeptidase concentrations of 1.25 × 10^{-3} and 1.25 × 10^{-4} units/pmol of Bβ1-42 were employed. The reaction was terminated by adding 10 μL of a stock solution of 2.0 mol/L O-phenanthroline (Sigma) in absolute ethanol (final concentration 0.01 mol/L) and Bβ1-42 immunoreactivity was measured with antisera R142, R154, and 132.

The effects of carboxypeptidase B treatment of Bβ1-42 were also assessed by HPLC. Bβ1-42 (50 μg) in Tris-buffered saline, pH 7.4, was incubated at 23 °C for 60 minutes with a final carboxypeptidase B concentration of 1.0 × 10^{-4} units/pmol of Bβ1-42. Under the same conditions the experiment was repeated with a carboxypeptidase B concentration of 1.0 × 10^{-3} units/pmol of Bβ1-42.

Generation of Bβ1-42 in Vitro

Recombinant human tissue plasminogen activator (rt-PA; Genentech, San Francisco, Calif) diluted in Tris-buffered saline, pH 7.5, with 0.1 mg/mL Tween 20 (Fisher), was incubated at 37 °C with 2 mL citrated plasma. At intervals, aliquots were removed, aprotinin (100 U/mL) was added, and the samples were precipitated with 50% ethanol, processed as described above and assayed for Bβ1-42 (using antiserum R142) and for FPA The experiment was repeated first using citrated plasma that had been preincubated with 0.1 U/mL of a purified fraction of reptilase (a gift of Dr B. Blomback) for 10 minutes at 23 °C before the addition of rt-PA, and then with citrated plasma to which reptilase and rt-PA were added simultaneously. The reptilase produced a visible clot within 90 seconds.

RESULTS

Characterization of the Antisera

Purified Bβ1-42 and β15-42 were conjugated to bovine serum albumin and used as immunogens in rabbits. Two of four rabbits receiving the Bβ1-42 immunogen responded. One antiserum, designated R142, showed the highest titer and was employed in this study. Fig 1A shows the reactivity of this antiserum with the various β-chain competitors. There was complete cross-reactivity between Bβ1-42 and Bβ1-21 while FPB, β15-42, and the other β-chain competitors (β12-42, β12-19, β22-42) did not react.

In contrast, although eight rabbits received the β15-42 immunogen, all produced low titer antisera after repeated booster immunizations and four died of unknown causes during a four-month period. Only one antiserum, designated R154, exhibited a sufficient titer to be employed in a radioimmunoassay. Competitive binding studies using this antiserum and ^{125}I-β15-42 as tracer are shown in Fig 1B. There was complete cross-reactivity among Bβ1-42, β15-42, and β22-42 while FPB and Bβ1-21 exhibited little reactivity.

Plasmin Cleavage of the β-chain of Fibrinogen

In a previous report[13] the sequence of plasmin cleavage of the NH_2-terminal region of the Bβ-chain of fibrinogen was studied using HPLC methods. Because of the specificity of

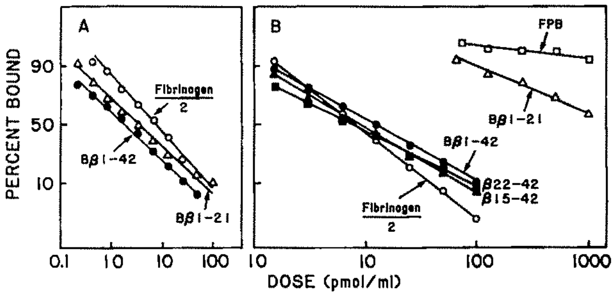

Fig 1. Competitive binding curves. (A) Using antiserum R142 and ^{125}I-Bβ1-42 as tracer. (B) Using antiserum R154 and ^{125}I-β15-42 as tracer.

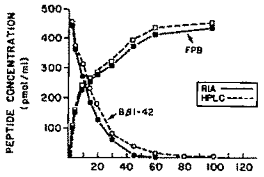

Fig 2. Thrombin proteolysis of Bβ1-42. Purified Bβ1-42 (22 μg/mL) was digested with thrombin (1.0 U/mL) and radioimmunoassays (RIA), employing antisera R142 and R22, were used to measure Bβ1-42 and FPB, respectively. HPLC was used in parallel to quantitate these peptides.

antiserum R142, these results could now be confirmed using radioimmunoassay, as well as HPLC techniques, to monitor Bβ1-42 release. Immunoreactivity, as measured using antiserum R142, reached a maximum between 40 and 60 minutes reflecting quantitative peptide release. HPLC was employed to separate and quantify the β-chain fragments. Bβ1-42 levels, as measured using HPLC, increased in parallel with immunoreactivity during the early stages of the digestion, reached a maximum, and then began to decline. As reported previously,[13] increasing levels of Bβ1-21 were seen following the initial Bβ1-42 release. The radioimmunoassay utilizing antiserum R142, which cross-reacts completely with Bβ1-42 and Bβ1-21, measured both of these peptides.

Kinetic Studies

Figure 2 illustrates thrombin proteolysis of purified Bβ1-42. The disappearance of Bβ1-42 immunoreactivity, measured using antiserum R142, was mirrored by the subsequent appearance of FPB immunoreactivity quantitated with R22 antiserum. HPLC measurements of these two peptides were in good agreement with the immunochemical data. The estimated kinetic constants for plasmin-mediated cleavage of the Bβ42-43 bond of the intact fibrinogen molecule and thrombin proteolysis of the Bβ14-15 bond of Bβ1-42 are listed in Table 1.

Recovery of Bβ1-42 in Blood and Plasma

The recovery of various concentrations of Bβ1-42 (50, 25, 12.5, 6.3, and 3.2 pmol/mL) added to blood and measured directly (employing antiserum R142) was compared with TIFPB determination. The Bβ1-42 assay gave a mean recovery of 114% as compared to 83% with the TIFPB assay.

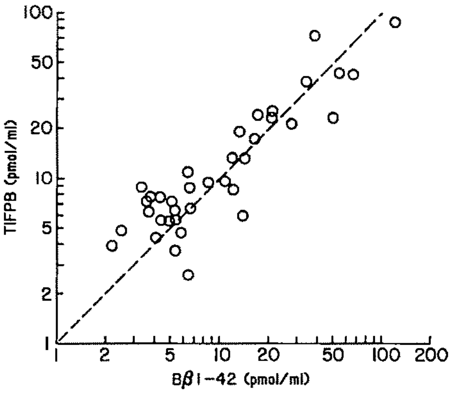

Fig 3. Comparison of plasma Bβ1-42 levels with thrombin increasable fibrinopeptide B immunoreactivity (TIFPB) in 37 patient samples. The coefficient of covariance is 0.91.

Similar results were obtained when Bβ1-42 was added to plasma with a mean recovery of 107% when quantitated as Bβ1-42 and 74% when measured as TIFPB. A comparison of the Bβ1-42 and TIFPB levels in 37 stored patient samples is illustrated in Fig 3. The coefficient of covariance is 0.91.

Bβ1-42 Concentration in Normals

The median Bβ1-42 level in 15 normal individuals was 1.2 pmol/mL with a 10% to 90% range of 1.1 to 1.7 pmol/mL. This correlates favorably with an estimated normal range for TIFPB of 1 to 4 pmol/mL.[11] In contrast, employing antiserum 132, which does not distinguish between Bβ1-42 and β15-42, normal levels of 0.4 pmol/mL were reported.[12] To explore this discrepancy, the stability of Bβ1-42 immunoreactivity in plasma was studied.

Stability of Bβ1-42 Immunoreactivity

Bβ1-42 immunoreactivity was stable in plasma over a 60-minute incubation at 23 °C when measured with antiserum R154 (Fig 4A). In contrast, when antiserum 132 was employed, more than 50% immunoreactivity was lost. Since previous studies had shown loss of fibrinopeptide B immunoreactivity in blood due to cleavage of arginine (Bβ14) by carboxypeptidase-like activity,[22] the effect of porcine pancreas carboxypeptidase B on Bβ1-42 immunoreactivity was determined in a buffer system. Treatment of Bβ1-42 with carboxypeptidase B resulted in a loss of immu-

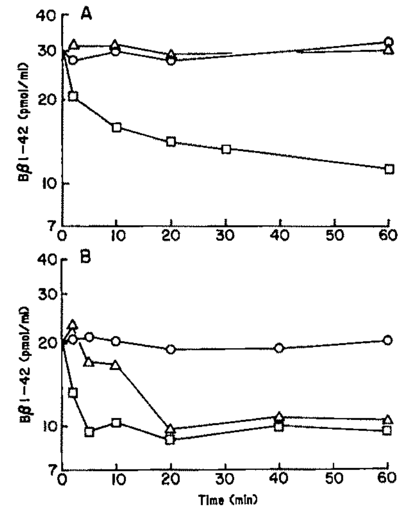

Fig 4. (A) Stability of Bβ1-42 immunoreactivity in plasma: Bβ1-42 (30 pmol/mL) was incubated in plasma at 23 °C. At intervals aliquots were removed, ethanol was added, and Bβ1-42 immunoreactivity was measured with antisera R142 (○), R154 (△), and 132 (□). (B) The effect of carboxypeptidase B on Bβ1-42 immunoreactivity with antiserum 132: Bβ1-42 (20 pmol/mL) was incubated in buffer, pH 7.4, at 23 °C without carboxypeptidase (○) or with 1.25 × 10^{-4} units/pmol (△) or 1.25 × 10^{-3} units/pmol (□) carboxypeptidase B. At intervals, aliquots were removed, o-phenanthroline (.01 mol/L) was added, and residual immunoreactivity measured.

noreactivity similar to that occurring in plasma when the Bβ1-42 was measured with antiserum 132 (Fig 4B). There was no loss of immunoreactivity when antisera R142 or R154 were employed. To determine whether this finding was a result of cleavage of the COOH-terminal arginine (Bβ42), native Bβ1-42 was treated with carboxypeptidase B and the digestion monitored by high performance liquid chromatography. Following 30 minutes of carboxypeptidase treatment (1.0 × 10^{-4} units/pmol Bβ1-42), two major peaks were identified and the corresponding peptides characterized by their amino acid content. One represented residual Bβ1-42 while the other (Table 2) showed loss of an arginine residue and thus was identified as Bβ1-41. Under the same conditions but with a higher carboxypeptidase B concentration, two peptide peaks were again seen. The major peak gave the amino acid analysis shown in Table 2, with loss of an arginine and tyrosine residue and thus was identified as Bβ1-40. The other peak represented a smaller peptide but amino acid analysis was not performed.

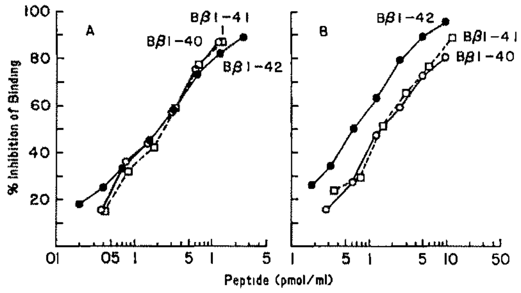

Fig 5. Cross-reactivity of Bβ1-42 and the isolated carboxypeptidase B degradation products. (A) The tracer was ^{125}I-Bβ1-42 and antiserum R142 was used. Inhibition curves for Bβ1-42, Bβ1-41, and Bβ1-40 are shown. 30% tracer was bound. (B) The tracer was ^{125}I-β15-42 and antiserum 132 was used. 32% tracer was bound.

The immunoreactivity of the carboxypeptidase B digestion products was studied using antisera R142 and 132. With antiserum R142 there was complete cross-reactivity between Bβ1-42 and the carboxypeptidase digestion products (Fig 5A). In contrast, when antiserum 132 was employed, Bβ1-41 and Bβ1-40 exhibited a two-fold loss of immunoreactivity as compared to Bβ1-42 (Fig 5B).

Immunochemic Analysis of Plasmin Proteolysis of Fibrinogen

Plasmin cleavage of the Bβ42-43 bond of fibrinogen and subsequent thrombin proteolysis of the Bβ14-15 bond of Bβ1-42 were assessed immunochemically using radioimmu-

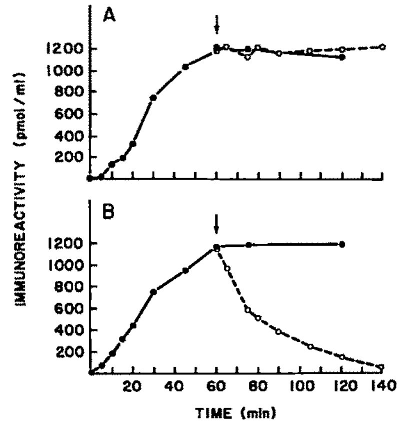

Fig 6. Immunochemical specificity of antisera R142 and R154. Fibrinogen (2.94 μmol/L), urokinase, and plasminogen were incubated at 27 °C. Samples were taken at various time points and immunoreactivity determined using antiserum R154 (A) and R142 (B). At 1 hour thrombin (1.0 u/mL) was added to half the reaction mixture (arrow) and immunoreactivity was monitored with (dashed line) and without (solid line) thrombin addition.

noassays employing antisera R142 and R154 (Fig 6). Proteolysis of fibrinogen by urokinase-activated plasminogen resulted in quantitative release of Bβ1-42 after 60 minutes when either assay was employed. The addition of thrombin to the reaction mixture at this point produced no change in immunoreactivity when determined with antiserum R154 (Fig 6A), whereas progressive loss of immunoreactivity occurred when antiserum R142 was utilized, reflecting thrombin cleavage of Bβ1-42 to FPB and β15-42 (Fig 6B).

Generation of Bβ1-42 in Vitro

When rt-PA was incubated with citrated human plasma, there was progressive generation of Bβ1-42 immunoreactivity (Fig 7A) with concentrations of rt-PA of 50 ng/mL plasma or higher. However, even with the highest concentration of rt-PA employed, this represented <1% of total releasable Bβ1-42 (plasma fibrinogen concentration was 7μmol/L). The plasma FPA concentration of 0.5 pmol/mL did not change throughout the incubation period. The experiment was then performed in plasma pretreated with reptilase (Fig 7B). Here fibrin I, rather than fibrinogen, was the substrate for plasmin action as was confirmed by demonstrating quantitative FPA release within 5 minutes of reptilase addition. Reptilase alone produced no significant Bβ1-42 cleavage but the addition of rt-PA at concentrations of 0.5 and 5 ng/mL, which resulted in no Bβ1-42 release in citrated plasma, produced slow generation of Bβ1-42 for 20 minutes followed by rapid Bβ1-42 release which was still increasing at 60 minutes. With 5 ng rt-PA/mL, less Bβ1-42 was released, but it was still more than that generated by 375 ng/mL in citrated plasma. To determine whether the 20-minute period of slow Bβ1-42 cleavage was due to mechanical limitation of rt-PA access to the fibrin I clot, a subsequent experiment was done in which rt-PA and reptilase were added to plasma simultaneously. This yielded results similar to those shown in Fig 7B.

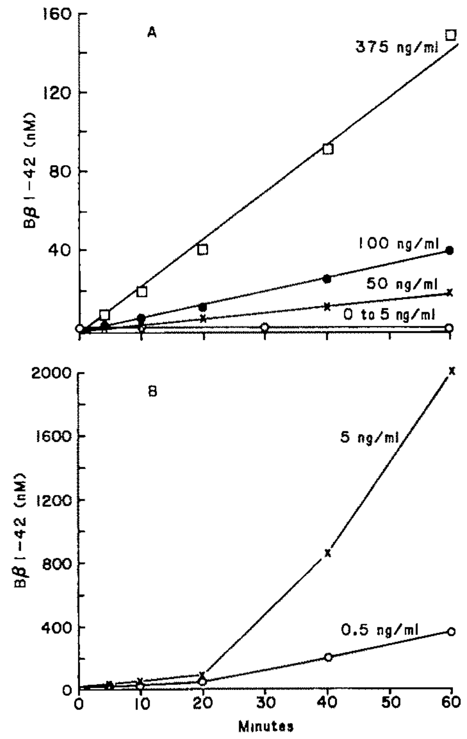

Fig 7. In vitro generation of Bβ1-42. (A) Bβ1-42 cleavage from fibrinogen by rt-PA–mediated plasminogen activation. Recombinant t-PA was incubated with citrated human plasma at 37 °C. At intervals aliquots were removed, mixed with aprotinin (100 U/mL), processed by precipitation with ethanol, and Bβ1-42 immunoreactivity measured with antiserum R142. (B) Bβ1-42 release from a fibrin I clot. The fibrin I clot was first formed by incubation of reptilase with plasma and then rt-PA was added and the mixture incubated at 37 °C. At intervals aliquots were removed, treated as described above, and the Bβ1-42 concentrations measured.

DISCUSSION

Since there is much evidence suggesting that the balance between thrombin and plasmin proteolysis of fibrinogen is an important determinant of normal hemostasis and thrombosis,[1] the development of radioimmunoassays for measurement of specific plasmin-derived fragments from the NH_2-terminal region of the Bβ-chain of fibrinogen permits a direct and quantitative approach to explore this hypothesis. Previous studies of plasmin proteolysis of this region indicated a sequence of events in which Bβ1-42 was the initial cleavage product. Once released from the parent fibrinogen molecule, Bβ1-42 underwent secondary plasmin attack but the kinetic data indicated that these latter cleavages were unlikely to be physiologically important. Whereas Bβ1-42 was the principal species released from fibrinogen or fibrin I by plasmin action, β15-42 was the major fragment cleaved by plasmin proteolysis of fibrin II.[13,23] With the concept that determination of Bβ1-42 levels would reflect plasmin action on fibrinogen or fibrin I while β15-42 levels would reflect proteolysis of fibrin II, we set out to develop specific radioimmunoassays to quantitate these peptides.

Antiserum R142, produced by immunizing with Bβ1-42, has an almost absolute requirement for the presence of an intact Bβ14-15 bond so that peptides lacking this bond are very poor competitors. This is illustrated in Fig 2, where thrombin cleavage of the Bβ14-15 bond of the Bβ1-42 molecule results in progressive loss of Bβ1-42 immunoreactivity which is mirrored by an increase in FPB immunoreactivity. These results are confirmed by HPLC quantitation of the peptides. Thus, the radioimmunoassays for Bβ1-42 and FPB provide an index of plasmin and thrombin activity, respectively, on the NH_2-terminal region of the Bβ-chain of fibrinogen. Recently, Kudryk et al[24] have reported on the preparation and use of a monoclonal antibody to the N-DSK fragment of human fibrinogen that may have an epitope in or around the thrombin-susceptible Bβ14-15 bond such that its specificity appears to be similar to that of antiserum R142.

That Bβ1-42 quantitated in the assay employing antiserum R142 provides a good index of fragment X formation was recently confirmed by a study correlating plasmin-mediated Bβ1-42 cleavage from fibrinogen with peptides released from the COOH-terminal region of the Aα chain. The loss of Aα-chain segments 540–554 and 259–276 coincided with proteolysis of Bβ1-42 measured with this assay. These data indicate that, during fragment X formation, there is simultaneous plasmin-mediated cleavage of the COOH-terminal Aα-chain and NH_2-terminal region of the Bβ-chain of fibrinogen.[25]

Because of the unique specificity of the radioimmunoassay employing antiserum R142, the kinetic data describing thrombin and plasmin proteolysis of Bβ1-42 could be estimated. The stability of Bβ1-42 in the presence of plasmin or thrombin activity in the blood can be explained by these data, which are summarized in Table 1. The Bβ42-43 bond of fibrinogen is the preferential plasmin cleavage site on the NH_2-terminal region of Bβ-chain[3,13,23] with the resultant release of Bβ1-42. Once released, this peptide is a relatively poor substrate for subsequent thrombin or plasmin attack. The selectivity constant (Kse = Kcat/Km) for plasmin cleavage of the Bβ21-22 bond of Bβ1-42 is 140-fold less than that for proteolysis of the Bβ42-43 bond of fibrinogen, suggesting that this hydrolysis is unlikely to be of physiologic importance. Similarly, the selectivity constant for thrombin cleavage of the Bβ14-15 bond of Bβ1-42 is 10^5-fold less than that for proteolysis of the same bond in the intact fibrinogen molecule.

In contrast to the unique specificity of antiserum R142, antiserum R154, obtained by immunizing with β15-42, cross-reacts with several peptides derived from the NH_2-terminal region of the Bβ-chain (Fig 1B). Almost no competition was seen using Bβ1-21, while parallel curves were generated with fragments Bβ1-42, β22-42, and β15-42, suggesting that the epitope for this antiserum is nearer to the COOH-terminal region of the peptide. Thus, its specificity is similar to that of antiserum 132[12] which has been employed in the development of a commercially available radioimmunoassay for quantitating fibrinogen/fibrin fragments containing the β15-42 sequence. Clinical studies utilizing this assay have been reported.[26,27]

The assay employing antiserum R142 gave consistently better recovery of Bβ1-42 added to blood or plasma than the indirect TIFPB assay. However, a comparison of these two methods for quantitation of Bβ1-42 in patient samples yielded a good correlation over a wide range of levels (Fig 3), indicating that TIFPB determination does indeed reflect Bβ1-42, thus validating the results of previous studies which employed this indirect assay.[11]

The discrepancy between the plasma levels of Bβ1-42 in normal individuals as measured in the assay employing antiserum R142 and those reported using antiserum 132,[12] which does not distinguish between β15-42 and Bβ1-42, is best explained by rapid removal of Arg (Bβ42) by plasma carboxypeptidase. This results in at least a 50% loss of Bβ1-42 immunoreactivity when quantitated with the latter antiserum (Fig 4). The finding that the carboxypeptidase digestion products, Bβ1-41 and Bβ1-40, exhibited two-fold less immunoreactivity than Bβ1-42 with antiserum 132 (Fig 5B), indicates that Arg (Bβ42) is an important determinant of the antigenic site. That removal of Tyr (Bβ41), in addition to Arg (Bβ42), resulted in no further loss of immunoreactivity suggests that conformational changes produced by removal of Arg (Bβ42) may be partly responsible for this loss. Although antiserum R154 also cross-reacted completely with Bβ1-42 and β15-42, Bβ1-42 immunoreactivity with this antiserum was stable in plasma and unaffected by in vitro carboxypeptidase treatment. This indicates that the antigenic determinant, although in the COOH-terminal region, is not dependent on Arg (Bβ42). Finally, since the epitope for antiserum R142 is in the region of the Bβ14-15 bond, immunoreactivity measured with this antiserum was unaffected by COOH-terminal degradation of the Bβ1-42 molecule (Fig 5A).

Radioimmunoassays employing antisera R142 and R154, when used in combination, provide a method for quantitating Bβ1-42 and β15-42 release from a variety of substrates. As illustrated in Fig 5, quantitative release of Bβ1-42, mediated by plasmin action on fibrinogen, was obtained using either radioimmunoassay. If thrombin was then added, there was rapid loss of Bβ1-42 immunoreactivity when antiserum R142 was utilized (Fig 5B), reflecting the requirements of this antiserum for an intact Bβ14-15 bond. In contrast, there was no loss of immunoreactivity when antiserum R154 was employed (Fig 5A). Therefore, in terms of plasmin proteolysis of the parent fibrinogen molecule, results obtained utilizing antiserum R142 reflect plasmin activity only on a substrate that has an intact Bβ14-15 bond, ie, fibrinogen or fibrin I. Since antiserum R154 has no such requirement, the result obtained with this assay reflects global plasmin activity regardless of whether the substrate is fibrinogen, fibrin I, or fibrin II.

The in vitro generation of Bβ1-42 was studied by the addition of rt-PA to plasma. The activation of plasminogen by tissue-type plasminogen activator is enhanced in the presence of fibrin.[28-30] The clot-selective properties of this agent have made it an attractive candidate for lytic therapy since it can produce clot lysis without depleting circulating fibrinogen, in contrast to the generalized lytic state produced by streptokinase or urokinase. Specific and quantitative assays for peptides released by plasmin proteolysis of the

NH_2-terminal region of fibrinogen and fibrin provide a method for differentiating the fibrinogenolytic effects of rt-PA from its fibrinolytic activity.

That the Bβ1-42 level is a sensitive index of plasmin-mediated proteolysis of fibrinogen is illustrated by progressive Bβ1-42 generation, without change in the FPA level, on addition of rt-PA to citrated plasma (Fig 7A). With the highest concentration of rt-PA employed there was cleavage of $<1\%$ of the total Bβ1-42 content from the parent fibrinogen molecule, consistent with the clot-selective properties of this agent. However, the finding that Bβ1-42 release was dose-dependent suggests that high plasma concentrations of rt-PA may produce significant fibrinogenolysis. In fact, this has been the reported experience with the administration of rt-PA for the treatment of venous thrombosis.[31] That low doses of rt-PA (0.5 and 5 ng/mL plasma) did not generate Bβ1-42 may be due to the presence of plasma inhibitors to t-PA[32,33] and/or plasmin.

The enhanced plasminogen activation by rt-PA in the presence of fibrin I is demonstrated by the significant Bβ1-42 release in reptilase-treated plasma with concentrations of rt-PA which had no effect in citrated plasma (Fig 7B). The period of slow Bβ1-42 release over the initial 20 minutes is unlikely to be due to mechanical limitation of rt-PA access into the fibrin clot since the simultaneous addition of rt-PA and reptilase produced similar results. A possible explanation relates to the finding that tissue plasminogen activator can induce plasminogen binding to fibrin I by catalyzing plasmin-mediated modification of the fibrin substrate and exposing new binding sites for Glu-plasminogen.[34]

In summary then, radioimmunoassays have been developed that can quantitate the products of plasmin cleavage of the NH_2-terminal region of the Bβ-chain of fibrinogen. The kinetic studies employing the specific Bβ1-42 assay explain the stability of Bβ1-42 in plasma, thus confirming the utility of measurement of this peptide. Because of carboxypeptidase-mediated degradation, the specificity of antisera to Bβ1-42 must be extensively explored prior to development of clinical assays for this peptide. Antiserum R154, because of its cross-reactivity with the carboxypeptidase-mediated degradation products, may prove useful in the development of a radioimmunoassay for global plasmin activity. Assays employing these antisera provide a direct and quantitative method to further explore the hypothesis that the balance between thrombin and plasmin proteolysis of fibrinogen is an important determinant of normal hemostasis and thrombosis. Further, they may prove useful in monitoring patients undergoing thrombolytic therapy.

ACKNOWLEDGMENT

The helpful discussions with Drs Karen Kaplan and John Owen and the expert technical assistance of Ms Teresa Santacroce are gratefully acknowledged. We thank Ms Helen Wegsman for typing this manuscript. This paper is dedicated to the memory of Dr Hymie L. Nossel.

Assessing the Delivery of Neutrophils to Tissues in Neutropenia

By D.G. Wright, A.I. Meierovics, and J.M. Foxley

Studies of neutrophil kinetics in neutropenic individuals, as well as clinical observations of variability in the occurrence of infection among patients with neutropenia, have suggested that blood neutrophil counts may not uniformly reflect the effective delivery of neutrophils to extravascular tissues where the cells perform their principal host defense functions. To evaluate this possibility we developed a sensitive, reproducible method of measuring the extravascular delivery of neutrophils to a normal mucosal site of neutrophil turnover. This method is based upon the quantification of neutrophils recoverable from saline mouth wash specimens. Twenty-five mL specimens, obtained in a controlled manner from neutropenic patients and normal subjects, were centrifuged and the sediments resuspended in 1.0 mL Hank's buffer with 2 μg acridine orange, incubated at 37 °C for 15 minutes, and then examined in a hemocytometer chamber by fluorescence microscopy. Neutrophils could be clearly distinguished by their characteristic fluorescence and were counted. With this method as few as 1,500 neutrophils were detected reliably in mouth wash specimens. Mucosal neutrophil counts varied less than 10% with repeated sampling of individual subjects over 5-day periods and were consistently greater than 1.3 × 10^5/specimen in non-neutropenic individuals. Although profound neutropenia was generally reflected by lower than normal oral mucosal neutrophil counts, these counts were significantly higher in individuals with chronic severe neutropenia (blood neutrophils <300/mm^3) than in patients with acute neutropenia of comparable severity that had developed following chemotherapy. Also, in individuals recovering from profound neutropenia, neutrophils usually reappeared earlier in mouth wash specimens than in blood, and oral mucosal neutrophil counts attained recovery levels more rapidly than did blood counts. This phenomenon was particularly evident in an individual with cyclic neutropenia. Moreover, mucosal neutrophils could occasionally be detected in profoundly neutropenic patients when neutrophils were not present in blood samples. These findings indicate that mucosal neutrophil counts in individuals with neutropenia provide information about the delivery of neutrophils to tissues that may not be apparent from blood neutrophil counts alone.

© 1986 by Grune & Stratton, Inc.

IT IS well known that neutropenia is associated with an increased risk of bacterial and fungal infections, particularly when blood neutrophil counts are less than 500/mm^3. However, neutropenic individuals may vary considerably in their apparent susceptibility to infection. The incidence and severity of infections are especially variable among individuals with chronic neutropenias. The clinical courses of such individuals are often remarkably benign despite profound neutropenia, unlike the usual experience of patients with an equivalent degree of neutropenia that is of acute onset following myelotoxic chemotherapy or radiation.[1-3]

Variability in the susceptibility to infection in neutropenia suggests that blood neutrophil counts may not uniformly reflect either the body's supply of neutrophils or the delivery of neutrophils to extravascular tissue sites where the cells perform their principal host defense functions. Furthermore, studies of neutrophil kinetics in both neutropenic and normal individuals, using techniques dependent upon the measurement of radiolabeled neutrophils in the circulation, have shown that an acute or chronic redistribution of neutrophils from marrow storage to the intravascular space and/or between circulating and marginated pools may cause variations in blood neutrophil counts that do not reflect changes in the body's total neutrophil supplies or the neutrophil turnover rate.[4-8] It has been observed in particular that the proportion of neutrophils in the marginated pool tends to increase as blood neutrophil concentrations decrease both in normal subjects[4] and in neutropenic patients.[6] These observations also suggest that blood neutrophil counts by themselves may be misleading with respect to the actual availability of neutrophils to tissues in neutropenic individuals. Studies of the delivery of neutrophils to tissues using the Rebuck skin window technique have in general demonstrated an impairment of neutrophil delivery to tissues in profoundly neutropenic patients.[1,9,10] However, this technique, which is time consuming and difficult to standardize, is unlikely to be able to detect differences in the delivery of neutrophils to tissues that may exist among individuals with similar degrees of neutropenia, nor is it readily applicable to the study of patients with profound neutropenia associated with myelosuppression and thrombocytopenia.

In order to examine variations in the delivery of neutrophils to extravascular tissues that may exist in neutropenia, we developed a method of quantifying neutrophils that can be washed from the oral mucosa. This method is a refined version of a technique that has been used for some time to provide a semiquantitative measure of periodontal disease severity in hematologically normal individuals.[11,12] Using this method, we find that mucosal neutrophil counts provide information about the delivery of neutrophils to tissues that may not be apparent from blood neutrophil counts alone. We find, in particular, that the supply of neutrophils to tissues as reflected by mucosal neutrophil counts is frequently underestimated by blood neutrophil counts in patients with chronic neutropenias and during the early phases of recovery from acute neutropenic episodes.

MATERIALS AND METHODS

Study subjects. Twenty-seven healthy men and women between the ages of 22 and 58, with a normal oral and pharyngeal exam and with teeth in good repair, were studied to define a normal range for measurements of oral mucosal neutrophil counts. Mucosal neutrophil counts were also measured in two men and two women (ages 51 to 60) who were edentulous but otherwise in good health. These

healthy individuals were specifically without clinically evident oral mucosal disease or symptoms, and all had normal blood neutrophil counts (2000 to 6000/mm^3) at the time of study.

Twenty-six individuals with either acute or chronic neutropenia, who were patients at the Walter Reed Army Hospital, were also studied. Of these, eight had only mild to moderate degrees of neutropenia (between 500 and 1800/mm^3) at the time of study and 17 had blood neutrophil counts in the severely neutropenic range (0 to 300/mm^3). Acute neutropenias were in all cases the result of myelosuppressive chemotherapy given within seven days of the onset of neutropenia. All patients with chronic neutropenias were known to have had neutropenia for at least 2 months prior to study. Underlying conditions in these neutropenic subjects are summarized in Table 1.

Patients and healthy volunteers were intentionally selected such that the study populations would be free of moderate or severe oral mucosal disease. The oral mucosa was examined in potential study subjects and the status of mucosal tissues was estimated by defining a gingival index.[9] The scoring criteria for determining this gingival index were as follows: a score of 0 = an absence of inflammation in gingival tissues; 1 = mild inflammation, characterized by reddening of the tissues without change in texture; 2 = moderate inflammation, characterized by moderate glazing, redness, edema, and hypertrophy of gingival tissues with or without bleeding on pressure from a probe; 3 = severe inflammation, characterized by marked redness and hypertrophy with a tendency toward spontaneous bleeding, with or without ulcerations. All of the normal subjects had a gingival index score of 0, and none of the neutropenic subjects included in this study (other than a patient with cyclic neutropenia) had a gingival index score greater than 1 at the times that mucosal neutrophil counts were measured. All study subjects gave informed consent for the examinations that were performed in accordance with a human use protocol approved at Walter Reed.

Recovery and quantification of neutrophils from the oral mucosa. Neutrophils present in the tissues of the oral mucosa were quantified by counting these cells in timed, saline mouth wash specimens. After an initial evaluation of several variations in technique discussed below, the following basic method for obtaining and examining specimens was used. Sterile, normal saline solution (0.9 g%) was measured into 25 mL aliquots in sputum cups. Study subjects swirled these measured amounts of saline in their mouths for 30 seconds, timed by a stop watch, and then returned the specimen to the sputum cup. Duplicate specimens were obtained with each sampling, one specimen obtained immediately following the other. The specimens were then centrifuged at 200 g for 10 minutes (within one hour of sampling), the supernatants decanted and discarded, and the pellets resuspended with a pasteur pipette in 1.0 mL of Hank's balanced salt solution (without phenol red) which contained 2.0 μg/mL acridine orange (3,6-bis[Dimethylamino] acridium chloride hemi-[zinc chloride salt], Sigma, St. Louis, Mo). These sediment suspensions were then incubated for 15 minutes at 37 °C in a shaking water bath and again resuspended thoroughly with a pasteur pipette. A drop of each suspension was transferred to a hemocytometer chamber (American Optical, Buffalo, NY) and examined by fluorescence microscopy, using a 20 x, long focal length objective lens and 10 x ocular lenses.

Neutrophils were clearly distinguishable from extraneous cellular and microbial debris in the specimen by their characteristic orange granular fluorescence (Fig 1B). Rarely, budding yeast forms or epithelial cells showed some orange fluorescence but this was readily differentiated from that of neutrophils in the specimen. Monocytes were also observed to fluoresce after staining with acridine orange. However, the orange granular fluorescence and yellow-green nuclear fluorescence of monocytes is much less bright than that of neutrophils, and these cells are distinguishable both by cytofluorography[13] and by eye. In performing mucosal neutrophil counts, cells with equivocal fluorescence staining were not counted.

Non-Hodgkins lymphoma	4	Associated with CLL	2
Metastatic carcinoma of breast	3	Cyclic neutropenia	1
Metastatic carcinoma of bowel	1		
Total	14		12

The area that the 20 x microscope field covered on the hemocytometer grid (final magnification = 200 x) was determined to be 0.672 mm^2, defining a volume of 0.672 mm^3 per 10 fields. Total neutrophils seen in 10 separate microscope fields were counted, and the numbers converted to the neutrophil concentration in the mouth wash sediment suspension according to the following formula: Neutrophils in specimen = (number of cells/10 fields) × (1.49) × (10^3). For convenience, mucosal neutrophil counts were expressed in general as cells/10 microscope fields. In serial studies with patients, saline mouth wash specimens were always obtained at mid-morning (about 10 AM).

For certain studies, up to six successive mouth wash specimens were obtained, one immediately after the other; replicate specimens were also obtained at 15-minute intervals. To assess the accuracy of this fluorescence staining method for counting neutrophils, the method was also applied to counting neutrophils present in leukocyte suspensions prepared by dextran sedimentation of normal venous blood, for which the numbers of neutrophils, monocytes, and lymphocytes had been calculated separately from standard chamber counts and differentials of Wright-Giemsa stained cytopreps.

Peripheral blood neutrophil counts. For blood neutrophil counts, venous blood samples (5 mL) were collected into standard vacutainer tubes anticoagulated with EDTA (Vacutainer Systems, Rutherford, NJ). Blood smears stained by an automated method with Wright-Giemsa were prepared, and total white blood cell counts were determined by a Coulter particle counter (Coulter Electronics, Hialeah, Fla). Absolute neutrophil counts were calculated from total white blood cell counts and 200 cell leukocyte differentials done exclusively by one of two observers (DW or JF). In serial studies with patients and with normal volunteers, blood samples were routinely obtained shortly before the mouth wash specimens.

RESULTS

Recovery of oral mucosal neutrophils from healthy hematologically normal individuals. Neutrophils could be readily seen in Wright-Giemsa stained, cytospin preparations of oral saline rinses obtained from hematologically normal, healthy adults who were free of oral or dental disease (Fig 1A). However, in order to quantify these cells in a reproducible manner and with some degree of detection sensitivity, it was necessary to use a selective staining technique that would permit relatively small numbers of neutrophils to be clearly distinguished from a large and highly variable quantity of epithelial cells, cellular debris, and microbial flora. This was accomplished by exploiting the fluorescence staining properties of acridine orange, a stain upon which certain automated fluorescence activated leukocyte differential systems have been based.[13] As is illustrated in Fig 1B, neutrophils that have taken up this stain fluoresce

Fig 1. Oral mucosal neutrophils. brightly and stand out clearly under fluorescence microscopy. Because of their characteristic orange granular fluorescence, nuclear morphology, and size, neutrophils could be recognized and counted, even if present in very low numbers. By combining this staining technique with a standard hemocytometer chamber, it was possible to measure neutrophil concentrations reproducibly down to a detection threshold of approximately 1,500 neutrophils in an individual 25 mL mouthwash specimen. This fluorescence staining method was found to detect neutrophils accurately in a mixed leukocyte preparation over a broad range of cell concentrations (Fig 2).

Counts from two successive mouthwash specimens, one obtained immediately after the other, were averaged. Unexpectedly, the neutrophil count in the second of these successive specimens was not much lower on average than that in the first specimen (2nd specimen count = 92 ± 7% of 1st specimen count, mean ± SEM, n = 32), although neutrophil counts dropped markedly in subsequent mouth wash specimens obtained immediately thereafter (Fig 3A). Moreover, the mean values for two successive counts showed less variability than either count alone when normal volunteers were studied repeatedly at 1-day intervals. Addition of EDTA (10 mg %) to the saline rinse solution increased the recovery of neutrophils slightly (by 5% to 15%) but did not provide more reproducible mucosal neutrophil counts than did normal saline alone, which was more readily applicable to studies of neutropenic patients.

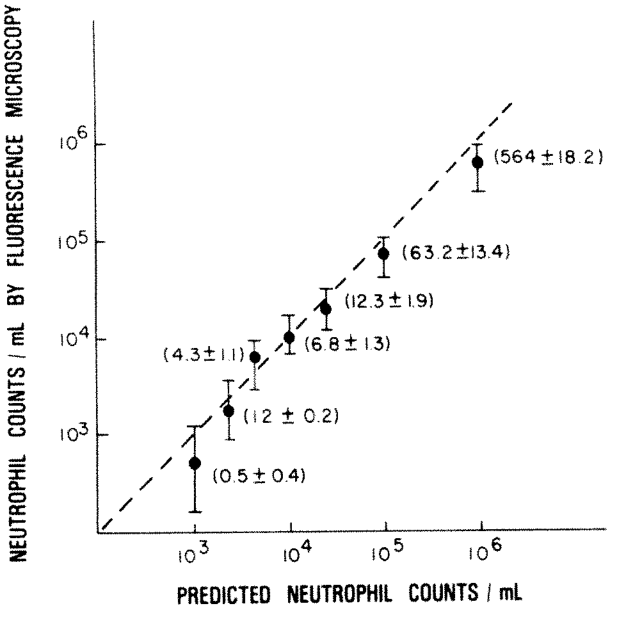

Fig 2. Neutrophil counts obtained by fluorescence microscopy of acridine orange stained suspensions of leukocytes (isolated from venous blood by dextran sedimentation) plotted against predicted counts. Samples for counting were prepared by multiple dilutions of a cell suspension with known neutrophil concentration (10^7/mL). This leukocyte suspension contained 75% neutrophils, 8% monocytes, and 17% lymphocytes. Numbers in parentheses represent neutrophils/10 microscope fields detected by fluorescence microscopy. Means ± SEM for 5 replicate determinations are shown.

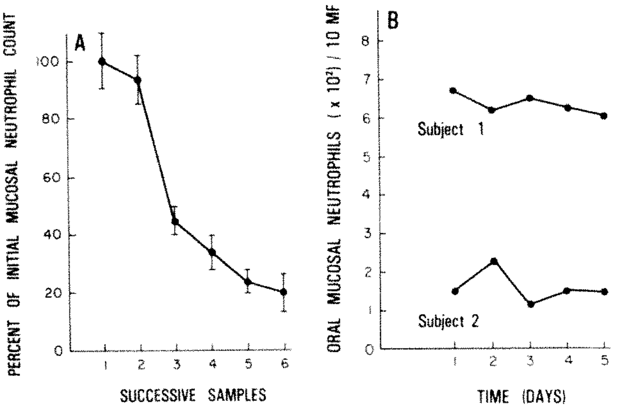

Fig 3. Repetitive oral mucosal neutrophil counts in normal individuals. (A) Mucosal neutrophil counts in successive mouth wash specimens, one taken immediately after the other. Results represent means ± SEM from 5 replicate studies. (B) Daily mucosal neutrophil counts in two healthy subjects whose blood neutrophil counts averaged 3,825 ± 219/mm³ (subject 1) and 2,670 ± 337 (subject 2).

Mouthwash samples from normal volunteers were found to contain up to 10.8 × 10^5 neutrophils and never less than 1.3 × 10^5/sample unless the individual was edentulous (see Fig 4A). Even in this group of study subjects with normal gingival indices and equivalent dentition, there was considerable variability in mucosal neutrophil counts from person to person, and only a very loose correlation between blood neutrophil counts and mucosal neutrophil counts (Fig 4A). However, there was much less variability in mucosal neutro-

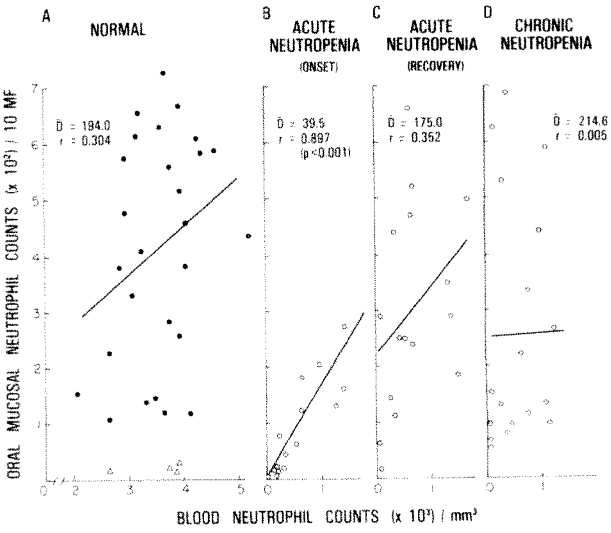

Fig 4. (A) Oral mucosal neutrophil counts in 31 healthy, nonneutropenic adults, 4 of whom (triangles) were edentulous. (B and C) In 5 patients with acute neutropenia during onset of neutropenia (3 data points from each patient), and during recovery from neutropenia (3 data points from each of 4 patients, 4 points from 1 patient). (D) In 8 patients with chronic neutropenia (2 data points from each of 6 patients and 3 points from each of 2 patients). Mucosal neutrophil counts are plotted against blood neutrophil counts obtained at the same time. phil counts obtained repeatedly from a single person on successive days. This variability was on average less than 10% for 6 normal subjects when studied on each of 5 successive days, or at intervals of greater than 2 hours. Representative results from these studies are shown in Fig 3B.

When mucosal neutrophil counts were obtained from normal subjects at 15-minute intervals (each count representing the average from two successive mouth wash specimens taken at each interval), it was found that the counts fell to a relatively stable level by the third set of samples. Pooled data from 5 normal subjects studied in this manner are shown in Fig 5. If one assumes that the reduced but stable level of mucosal neutrophil counts observed with successive mouth wash sampling represents a balance between the loss of cells that are washed from the mucosa and the arrival of new cells, then this level may be considered to reflect the rate at which neutrophils are delivered to the mucosal sites that are sampled.

Corticosteroids when taken daily have been shown to cause an impairment in the delivery of neutrophils to tissues, as measured by the Rebuck skin window assay.[14] This effect of corticosteroids could also be detected with mucosal neutrophil counts. In studies of healthy volunteers, it was found that mucosal neutrophil counts were significantly reduced 6 hours after a single dose of 40 mg prednisone (by 46 ± 12%, mean ± SEM from five replicate studies) even though blood neutrophil counts had more than doubled. As shown in Fig 5, the apparent rate of neutrophil delivery to the oral mucosa reflected by repeat counts at 15-minute intervals was also reduced by this corticosteroid.

Recovery of mucosal neutrophils from neutropenic individuals. Profound neutropenia (< 300/mm^3) was in general associated with decreased mucosal neutrophil counts compared with normal controls (Figs 4 B, C, D). However, as with normal individuals, there was considerable variability in mucosal neutrophil counts among individuals with comparable degrees of neutropenia, particularly in the mild to moderately neutropenic range (500 to 1800/mm^3). As shown in Figs 4 B, C, and D, the highest degree of correlation between blood neutrophil counts and mucosal neutrophil counts was observed in patients with acute neutropenia during the onset of neutropenia; such correlations were much looser in these same patients during recovery from neutropenia and were inapparent in data from patients with chronic neutropenias.

In patients with acute, severe neutropenia following myelosuppressive chemotherapy, neutrophils were commonly observed to reappear and return to a stable level earlier in the oral mucosa than in the blood. This phenomenon is illustrated in Fig 6A. An analogous phenomenon was very obvious in serial counts obtained from a young woman with cyclic neutropenia (Fig 7).

It was also observed that low but detectable numbers of neutrophils could be recovered occasionally from the oral mucosa in patients with no neutrophils evident in the blood on repeated sampling. An example of this is shown in Fig 6B, which presents data obtained from a patient who was observed for nine days to have no detectable neutrophils in the blood, and who then developed worsening clinical signs of

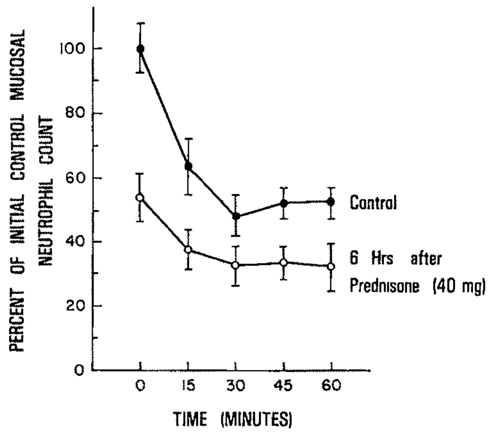

Fig 5. Mucosal neutrophil counts obtained at 15-minute intervals in healthy adults before (closed circles) and 6 hours after 40 mg prednisone P.O. (open circles). Blood neutrophil counts in these individuals were 268 ± 51% higher after prednisone. Results represent means ± SEM from 5 studies.

infection, despite broad spectrum antibiotics, prompting the institution of leukocyte transfusions. Of interest, it appeared that the effects of leukocyte transfusion could be detected in mucosal neutrophil counts in this patient Although it was not possible to prove in this case that the rise in blood and mucosal neutrophil counts observed with leukocyte transfusions reflected the presence of donor cells, this was highly likely since blood neutrophil counts returned to zero after a day's hiatus in leukocyte transfusions.

Patients with profound degrees of neutropenia (<300/mm^3) that was chronic (ie, established for ≥ 2 months) were distinguishable as a group from patients with acute neutropenias of comparable degrees of severity by the oral mucosal neutrophil counts. As shown in Table 2, mucosal neutrophil counts from patients with profound chronic neutropenias (0 to 100/mm^3 and 100 to 300/mm^3) were significantly higher than those from patients with acute neutropenias of comparable severity. It was possible that differences in the status of the oral mucosa in these two groups of patients contributed to this observation; however, such differences were not evident from clinical examination of the oral mucosa.

The relevance of mucosal neutrophil counts to the clinical status of these markedly neutropenic patients was suggested by relationships that appeared to exist between the blood and mucosal neutrophil counts and the presence or absence of fever. None of the patients with chronic neutropenias, whose blood and mucosal neutrophil counts are summarized in Table 2, were febrile when studied. In contrast, most of the acutely neutropenic patients represented in Table 2 were febrile at some time during their nadirs of neutropenia.

As has been pointed out above, one of the distinctions between these groups of patients was that mucosal neutrophil counts were on average substantially higher with respect to blood neutrophil counts for patients with chronic, profound neutropenias than was the case for patients who were acutely neutropenic. Moreover, when the relationship of mucosal neutrophil counts to blood neutrophil counts was expressed as a ratio (mucosal neutrophils per 10 microscope fields, divided by blood neutrophils per mm^3), it was found that this ratio was almost always > 1.0 for patients with chronic neutropenias, while it was frequently < 1.0 for the acutely neutropenic patients. Moreover, when individual patients were followed throughout episodes of myelosuppression following cytotoxic chemotherapy, it was observed that the highest degrees of fever tended to occur when the ratios of mucosal neutrophil counts to blood neutrophil counts were lowest, as exemplified by the data shown in Fig 6A.

Table 3 summarizes data from five patients who were studied repeatedly during chemotherapy-induced acute neutropenia. Mucosal and blood neutrophil counts were obtained from each of these patients on at least six separate days during their nadirs of neutropenia. These patients were febrile (≥ 38 °C) on 16 of 30 occasions (53%) when their neutrophil counts were studied; fever ≥ 38.5 °C was recorded on six occasions (20%). As might be expected, the highest fevers tended to occur more frequently with blood neutrophil counts of 0 to 100/mm^3 than with counts of 100 to 300/mm^3 ($P = 0.10$, Chi Square; $P = 0.18$, Fisher exact test). However, when these same data were examined with respect to the ratios of mucosal to blood neutrophil counts, it was found that fever (≥ 38.5 °C) was significantly more likely to be present when the mucosal/blood neutrophil ratio was ≤ 0.4 (the median value observed in these patients), both when all observations (blood neutrophils = 0 to 300/mm^3) were analyzed ($P < 0.01$, Chi Square; $P < 0.02$, Fisher exact test) and when subgroups of observations (blood neutrophils = 0 to 100/mm^3) were analyzed ($P < 0.05$, Fisher exact test).

DISCUSSION

It has long been recognized that neutrophils are normally present on mucosal surfaces, in saliva, and in tears. According to an old clinical adage, a patient's awareness of a dried conjunctival exudate at the corner of the eye upon awakening is a very early sign of recovery from agranulocytosis. Furthermore, it has been suggested that the presence of neutrophils in conjuctival secretions, or in a swab of the nasal mucosa, might provide useful information for assessing the relative risk of infection in a patient with profound neutropenia.[15] Animal studies have indicated that the delivery of neutrophils to mucosal tissues, particularly that of the gastrointestinal tract, accounts for a substantial proportion of daily neutrophil turnover,[16] and it would appear likely that a constant turnover of neutrophils at such sites constitutes an important component of mucosal barriers against the invasion of resident microbial flora, for when production and turnover of neutrophils cease, sepsis with organisms from this normal flora quickly ensues.

For the studies described above, we developed a method for quantifying mucosal neutrophils recoverable in mouth wash specimens. We then used this method to determine if mucosal neutrophil counts might provide information that is different from or supplemental to that provided by blood neutrophil counts in neutropenic individuals. There are a number of reasons to suspect that the measurement of neutrophils that have been delivered to a normal tissue site of turnover in neutropenic individuals might differ from that of blood neutrophils, which are in transit to tissues. First, if neutropenia is associated with substantial shifts in the proportion of neutrophils in the circulating pool to that of the

marginated pool, as has been suggested by neutrophil kinetic studies to be the case in neutropenia,[4,6] or if neutropenia is associated with a decrease in the transit time of neutrophils through the blood to tissues, then one can expect that blood neutrophil counts might underestimate the supplies of neutrophils available to tissues. Second, clinical observations of variability in the occurrence of infection among patients with acute and chronic neutropenias suggest that blood neutrophil counts may not uniformly reflect the effective delivery of neutrophils to extravascular tissues where the cells perform their principal host defense functions.

The results of our studies indicate that blood neutrophil counts do indeed underestimate the delivery of neutrophils to tissues in certain settings of profound neutropenia, particularly among individuals with chronic, steady-state neutropenias, and during early recovery from an episode of myelosuppression when neutrophil reserves and production are returning. An apparent discordance of blood neutrophil counts with the delivery of neutrophils to tissues was also detected by mucosal neutrophil counts in normal individuals who had taken corticosteroid. This finding is consistent with previous observations from studies using the Rebuck skin window technique.[14]

As would be expected, mucosal neutrophil counts indicated in general that the delivery of neutrophils to tissues is impaired in profound neutropenia. Moreover, a direct relationship between blood neutrophil counts and mucosal neutrophil counts was found to be particularly strong during the development of neutropenia following myelosuppression. This relationship, however, was much less apparent during recovery from myelosuppression and among chronically neutropenic patients in whom neutrophil production is preserved albeit at a limited level. The finding that neutrophils reappeared earlier in mucosal counts than in blood counts during myelopoietic recovery is consistent with the diminished correlation between blood and mucosal neutrophil counts that was observed during this phase of acute neutropenia.

Approximations of the relative numbers of neutrophils in mouth rinse specimens have been used to grade the severity of periodontal disease.[11,18] Nonetheless, the presence of neutrophils in saliva or on the oral mucosa is not per se an indication of mucosal pathology or oral infection, for these cells can be readily detected in healthy individuals with normal mucosal and gingival tissues and with normal dentition. The principal sites of the oral mucosa for neutrophil turnover are in alveolar crevices surrounding the teeth,[18] and our finding of relatively low numbers of oral mucosal neutrophils in edentulous but otherwise healthy people is entirely consistent with the prior observations of others.[18,19] Variations in the numbers of teeth were, however, unlikely to account for the variability in mucosal neutrophil counts observed among normal and neutropenic individuals, for all study subjects were selected for normal dentition and differed only with respect to the numbers of wisdom molars that were missing.

Counts of oral mucosal neutrophils have been studied

previously as a means of assessing the effects of leukocyte transfusions[20]; however, the techniques used in these prior studies were not of sufficient sensitivity to detect either endogenous or transfused neutrophils in profoundly neutropenic individuals except when clinically evident oral mucositis was present. The techniques developed for our present studies, on the other hand, proved to be sufficiently sensitive to detect the presence of mucosal neutrophils even, in some cases, when neutrophils were undetectable in the blood.

Differences in the status of the oral mucosa could account in part for differences in the numbers of oral mucosal neutrophils that were observed among patients with acute and chronic neutropenias, for it is well known that individuals with chronic neutropenias tend to develop recurrent stomatitis and periodontal disease, as was the case in the patient with cyclic neutropenia described in this report. However, if there were differences in the oral mucosa among our study subjects, they were not apparent by direct inspection alone. These subjects were intentionally selected to be free of gingival and dental disease in order to eliminate mucosal inflammation as an independent variable as much as possible.

In any case, our observations are of interest because individuals with chronic, established neutropenias, even when profound, tend to present a relatively benign clinical picture compared with patients who develop acute neutropenia following myelosuppressive chemotherapy.[3] Patients with chronic neutropenias rarely develop sudden, overwhelming sepsis or septicemias,[1,2] and this clinical distinction is consistent with a difference in the effective delivery of neutrophils to normal mucosal sites of neutrophil turnover.

It has been suggested that monocytes, which are often preserved in chronic neutropenias and may be increased in number, may assume some of the host defense functions of neutrophils, thereby accounting for the relatively mild host defense defect that is often apparent with chronic neutropenia.[10] Monocytes could possibly have masqueraded as neutrophils in the mucosal counts performed on chronically neutropenic study subjects. However, it is unlikely that monocytes accounted for much, if any, of the mucosal neutrophil numbers detected in these patients since the fluorescence staining technique used distinguishes neutrophils from monocytes fairly efficiently.

The apparent relationship between the ratio of mucosal to blood neutrophil counts and the presence or absence of fever in profoundly neutropenic patients is intriguing. Certainly, it is attractive to suppose that a direct measure of the delivery of neutrophils to tissues might supplement blood neutrophil counts in predicting the extent of a host defense defect and the risk of infection in such patients. However, our findings must be interpreted cautiously in this regard, since these studies were not specifically designed to address the question of infection risk. Moreover, the neutropenic patients who were studied represent a selected population. Nonetheless, our findings do suggest that the quantitative measurement of mucosal neutrophils deserves further consideration and study as a clinically useful tool in neutropenic patients.

Modulation of In Vitro Growth of Murine Myeloid Leukemia by an Autologous Substance Immunochemically Cross-Reactive With Insulin and Antiinsulin Serum

By Z. Vuk-Pavlović, K. Pavelić, and S. Vuk-Pavlović

Murine myeloid leukemia secretes a substance immunochemically cross-reactive with insulin (SICRI) both in vivo and in serum-free media. High SICRI concentrations in peripheral blood of tumorous animals do not affect circulating glucose levels. In culture, DNA synthesis rate per leukemic cell is proportional to cell density and is reduced by antiinsulin serum. Culture medium conditioned by leukemia cells as well as SICRI affinity purified from this medium stimulate DNA synthesis in cultured leukemia cells. It appears that autocrine stimulation of murine myeloid leukemia can be mediated in part by an insulin-related growth factor.

© 1986 by Grune & Stratton, Inc.

PROGRESSION of several human tumors is paralleled by elevated blood levels of substances immunochemically cross reactive with insulin (SICRI).[1-5] SICRI production in tumorous diabetics[2,3] and by cultured tumor cells[4] demonstrate that this substance is indeed of tumor origin. On the basis of circumstantial evidence, we speculated that SICRI might mediate tumor autostimulation by an endocrine and/or autocrine mechanism.[5-7]

Autostimulation in murine melanoma B16, a SICRI-secreting tumor, was recently quantitated by mathematical modeling.[8] However, this phenomenologic mathematical model cannot reveal the mechanistic involvement of SICRI in autostimulation. Here, in murine myeloid leukemia (MML),[9] we demonstrate in vitro the autocrine growth control partially mediated by SICRI.

MATERIALS AND METHODS

Male RF mice, eight to ten weeks old, were obtained either from Rugjer Bošković Institute, Zagreb, or from Jackson Laboratory, Bar Harbor, Me. They were kept five per cage and fed standard pelleted food and water ad libitum. Myeloic leukemia was maintained by IV inoculations of 1×10^6 cells obtained from spleens of diseased animals. Blood was drawn by axillar exsanguination. Cellularity of spleen was determined by weighing spleens by use of a Mettler microbalance and by counting suspended splenocytes in a hemocytometer.

Insulin and SICRI concentrations were determined by commercial double-antibody insulin-specific radioimmunoassay (RIA: Serono, Saluggia, Italy) or by kits assembled using commercial polyclonal antibodies (Cappel, Malvern, Pa) and A_{14}-monoiodotyrosine insulin (360 μCi/mg; Eli Lilly, Indianapolis, Ind). Therefore, SICRI concentrations are relative and expressed as insulin equivalents RIA artifacts were excluded by control experiments: (1) Incubation of ^{125}I-insulin with tumor extracts or concentrated conditioned tissue culture media (*v infra*) for 12 hours of room temperature (RIA conditions) neither significantly decreased the amount of phosphotungstic acid precipitable material nor changed the position of the radioactive peak in the eluates of these samples from a Protein Analysis I-125 HPLC column (Waters Associates, Milford, Mass). These experiments show the absence of falsely elevated SICRI concentrations due to ^{125}I-insulin degradation; (2) SICRI preparations failed to increase the amount of ^{125}I-insulin precipitated by 14% polyoxyethylene 6000 (POE) after 12 hours' incubation, demonstrating the absence of ^{125}I-insulin binding materials in these preparations; (3) Substitution of the second antibody by 18% POE and 1 mg/mL human IgG resulted in the same values as obtained by double-antibody RIA showing that SICRI containing samples do not interfere with binding of the second antibody. Growth hormone concentrations were measured by commercial double-antibody RIA (Serono, Saluggia, Italy). Glucose concentrations were measured by the glucose oxidase-peroxidase method (Sigma, St. Louis, Mo).

Spleens were weighted and homogenized in nine parts of phosphate-buffered saline, pH 7.5. The homogenate was centrifuged for 10 minutes at 10,000 g and SICRI in the supernate was measured by insulin-specific RIA.

Murine myeloid leukemia cultures were established from the leukemic spleen of a RF mouse. A cell suspension was prepared by passing tumor tissue through a nylon mesh and several times through a gauge 21 needle and cells were grown at 37 °C in serum-free transferrin-supplemented (5 mg/L; Sigma) Iscove's modified Dulbecco's medium (Sigma) in 5% CO_2. The medium was changed every second day. The first medium change was discarded and the subsequent ones were used as the source of SICRI.

Stimulation of DNA synthesis by growth factors was measured in cells grown in Costar (Cambridge, Mass) 96-well clusters by measuring [methyl-^{3}H]-thymidine (specific activity 2 Ci/mmol, 1 mCi/mL; Research Products International, Mt. Prospect, Ill) incorporation. The original [^{3}H]-thymidine solution was diluted tenfold with the cell culture medium and a dose of 0.2 μCi of [^{3}H]-thymidine in 2 μL was added to each well. Duration of incubation with [^{3}H]-thymidine is indicated in the legends to Figs 2 and 3 and Table 1. Cells were harvested using a Bellco cell harvester. Radioactivity of incorporated thymidine was measured by use of 3a70 scintillation cocktail (Research Products International, Mt. Prospect, Ill) and Packard Tri-Carb Liquid Scintillation Spectrometer.

SICRI preparations assayed for effects on [^{3}H-methyl]-thymidine incorporation by MML cells were obtained from serum-free tissue culture medium conditioned by tumor cells and concentrated by use of an Amicon UM2 membrane. This concentrated medium was dialyzed against PBS, pH 7 4, and used for cell culture experiments or was applied to a column of affinity purified guinea pig antiporcine insulin antibodies immobilized on Affi-Gel 10 (Bio Rad) according to manufacturer's instructions. The column was extensively washed with PBS and the bound material was eluted with 1.0 mol/L acetic acid. The eluate was neutralized immediately with 2 mol/L sodium hydroxide and dialyzed against PBS in Spectrophor dialysis bags (M.W. cut-off = 1000; Spectrum Medical Industries, Los Angeles, Calif).

The apparent relative molecular mass (M_r) of native SICRI was estimated by gel filtration of the concentrated conditioned medium on a 0.9 × 50 cm Sepharose B6 column. PBS containing 0.3 mg/mL bovine serum albumin at a flow rate of 10 mL · cm^{-2} · hr^{-1} was used

as the mobile phase. Blue dextran, human IgG, human serum albumin, bovine ^{125}I-insulin, and potassium ferricyanide were used for column calibration. The fractions in PBS were assayed by RIA directly and those in 1 mol/L acetic acid only after removal of the acid by freeze drying and reconstitution with the RIA buffer.

Cell colonies were established in soft agar in 35 × 10 mm Petri dishes. The solidified bottom layer [2.5 mL of 0.5% agar in Dulbecco's modified Eagle's medium (DMEM) supplemented as indicated in Table 2] was overlaid with 0.85 mL of DMEM containing 5 × 10^4 MML cells and 0.3% agar. Monocomponent porcine insulin (Novo, Copenhagen, Denmark), SICRI, FCS, human transferrin (Sigma, St. Louis), and selenous acid (Sigma) were added at concentrations indicated in Table 2. Quadruplicate cultures were incubated at 37 °C in water-saturated air supplemented with 5% CO_2 for four days. Colonies were defined as clusters of more than 30 cells. Statistical analysis was performed by the Student's *t* test.

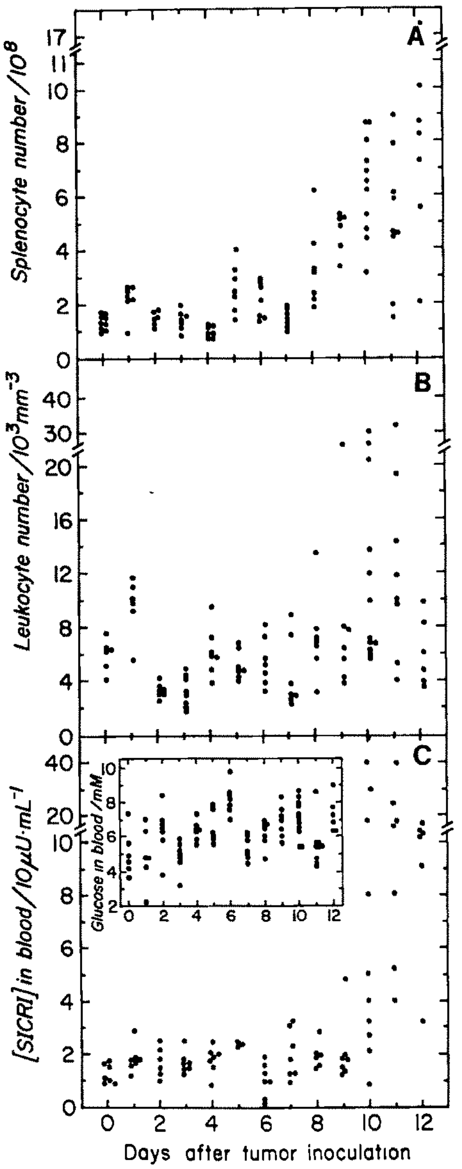

Fig 1. The time course of change of splenocyte number (A), peripheral blood leukocyte number (B), and of circulating SICRI (C) and glucose concentrations (inset) in mice IV inoculated with 1 × 10^6 myeloid leukemia cells on day 0.

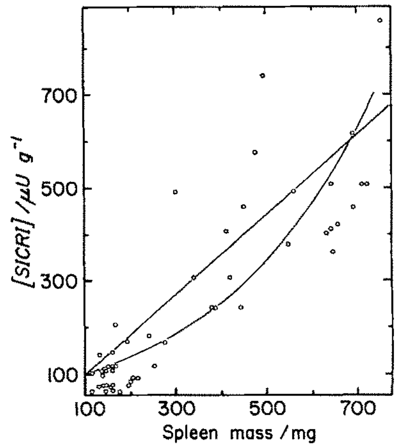

Fig 2. Intracellular SICRI concentration normalized per gram of wet spleens of RF mice suffering from myeloid leukemia as a function of spleen mass. Least-square fitting procedures yielded relationships [SICRI] = 850 M_s + 10.68 with R = 0.77 (straight line), and [SICRI] = 75.98 exp (3.01 M_s) with R = 0.76 (curved line), where SICRI concentrations are expressed in μU of insulin equivalents per gram of wet spleen and spleen mass, M_s, in grams.

RESULTS AND DISCUSSION

When one million murine myeloid leukemia cells were injected IV in RF mice, the animals died 12 days later.[10] Within the first seven days after inoculation, the spleen mass, number of peripheral leukocytes, and insulin levels in peripheral blood remained virtually normal. However, from the eighth day, these three parameters increased dramatically reaching maxima on the tenth day. Glucose levels did not change under the same circumstances (Fig 1). All these parameters, except glucose, decreased somewhat near the end of the survival period (days 11 and 12) when the animals were evidently cachectic. Growth hormone concentrations in peripheral blood were not affected by the disease.

We measured SICRI concentrations in homogenized leukemic spleens. In Fig 2, SICRI concentrations normalized per g of wet spleen tissue are plotted as a function of spleen

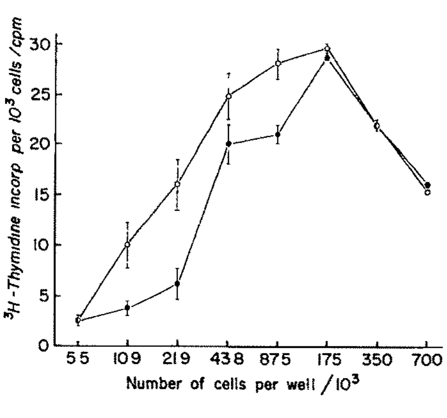

Fig 3. [^{3}H-methyl]-thymidine incorporation by murine myeloid leukemia cells in absence (○) and presence (●) of 1:1,000 diluted guinea pig antiporcine insulin antiserum as a function of cell density. Cells suspended in 0.2 mL of Iscove's modified Dulbecco's medium were placed in wells of Costar 96-well clusters. To each well 0.2 μCi of [methyl-^{3}H]-thymidine was added at the beginning of the 12-hour incubation.

mass. These data show that the increase of spleen mass, due to colonization by leukemic cells,[11] is paralleled by an increase of SICRI concentration in whole cell homogenate.

From the spleen of a tumorous mouse, we established the primary leukemia culture and propagated it in serum-free transferrin-supplemented (5 mg/L) Iscove's modified Dulbecco's medium (IMDM). These cultures were serum independent and they secreted SICRI into the medium. After three days of cultivation, media harvested from confluent cultures contained SICRI in concentrations up to 50 µU/mL.

The presence of autocrine growth promoting activity in media of MML cells was established by monitoring [methyl-^{3}H]-thymidine incorporation by MML cells as a function of cell density, both in presence and absence of antiinsulin serum for 12 hours (Fig 3). The normalized DNA synthesis rate, as measured by thymidine incorporation per cell, depended strongly on cell density: at densities up to 1×10^5 cells/well, it was proportional to the number of cells, while at higher cell densities, it was inversely proportional. The addition of antiinsulin serum (1:1,000 dilution) to these cultures interfered with DNA synthesis throughout the range of synthesis proportional to cell density (Fig 3). Indeed, up to the density of $\sim 2 \times 10^4$ cells/well, this serum almost completely inhibited DNA synthesis. To evaluate whether these inhibitory effects are due to toxicity of antiinsulin serum, we performed experiments with longer incubation with the antiserum (Table 1). Thirty thousand cells were incubated for 24 (rather than 12) hours with different dilutions of antiserum. Then [^{3}H]-thymidine was added for three more hours. Although different experimental conditions preclude other comparisons between data in Fig 3 and Table 1, it is obvious that the 1:800 serum dilution was not cytotoxic (Table 1); therefore, data in Fig 3 reflect neutralization of SICRI by antiinsulin serum. Moreover, data in Table 1 showed that this effect of serum depended on serum concentration and that at 1:200 dilution it could reduce the DNA synthesis by one half (Table 1). It appears, therefore, that stimulation of the DNA synthesis rate is due to a higher concentration of autocrine growth factors at higher cell densities. The inhibitory effects of antiinsulin serum not only support this notion, but demonstrate the existence of an insulin-related growth factor.

By use of concentrated and dialyzed IMDM conditioned by MML cells, we were able to modulate MML growth in vitro (Fig 4). The addition of SICRI up to 64 µU/mL stimulated DNA synthesis by MML cells; at higher concentrations DNA synthesis was reduced. Qualitatively identical data were obtained by use of SICRI, affinity purified from MML-conditioned medium on an antiinsulin-agarose column (inset to Fig 4). The extent of stimulation of DNA synthesis by this preparation is smaller than by unfractioned conditioned medium, yet the maximum stimulation is obtained at the same SICRI concentration (64 µU/mL). Moreover, like the cells treated with crude conditioned medium, the cells treated with affinity-purified SICRI showed a diminished incorporation of thymidine at SICRI concentrations above 64 µU/mL. This type of biphasic concentration-response relationship is similar to that seen with other growth-promoting substances.[12]

Table 1. Effect of Antiinsulin Antiserum on Growth of Cultured MML Cells

Dilution	[Methyl-^{3}H]-thymidine Incorporation/cpm Normal Guinea Pig Serum	 Guinea Pig Antiinsulin Antiserum	Inhibition/%
1/800	2035 ± 244	2077 ± 192	0
1/400	2375 ± 232	1839 ± 122	23
1/200	2190 ± 255	1158 ± 94	47

In each well 30,000 cells in 0.2 mL IMDM were incubated with sera for 24 hours when 0.2 µCi [methyl-^{3}H]-thymidine in 2 µL was added. Cells were harvested three hours later.

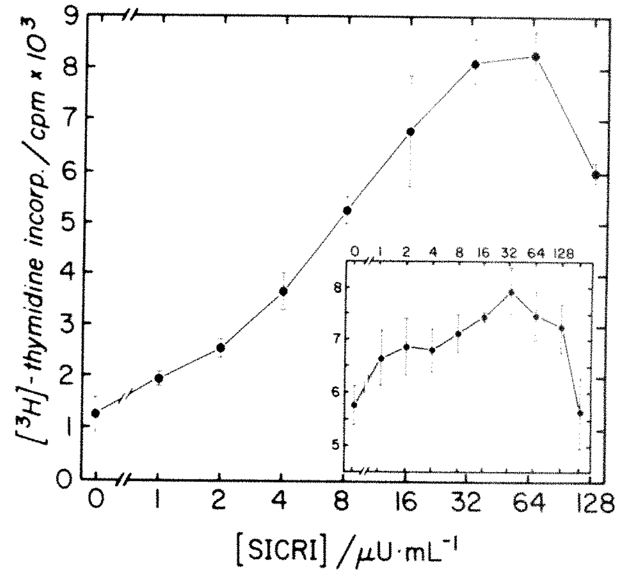

Fig 4. [^{3}H-methyl]-thymidine incorporation by 3×10^4 murine myeloid leukemia cells as a function of SICRI concentration. SICRI was added either in the form of concentrated and dialyzed (through a MW cut-off = 1000 membrane) medium conditioned by myeloid leukemia cells or as an affinity-purified preparation from the same conditioned medium (inset). Cells were incubated with SICRI for 12 hours when [methyl-^{3}H]-thymidine was added for 5 more hours.

We compared the effects of SICRI and insulin on colony formation by MML cells in soft agar (Table 2 and Fig 5). Insulin (0.25 µU/mL) did not stimulate colony formation, but the equivalent concentrations of SICRI exerted significant stimulation ($P < 0.01$). This finding is in full agreement with results of analogous experiments performed with melanoma B16 cells[16] and L1210 cells (K. Pavelić, unpublished results).

Table 2. Effects of Insulin and Affinity-Purified SICRI on Colony-Forming Ability of MML Cells in Soft Agar

Treatment	Number of Colonies
DMEM	98 ± 16
DMEM + 10% FCS	479 ± 70
Insulin (0.25 µU/mL)	128 ± 26
SICRI (0.25 µU/mL)	237 ± 46
SICRI (0.50 µU/mL)	336 ± 58

Human transferrin (5 mg/L) and selenous acid (25 µg/L) were added to media without FCS.

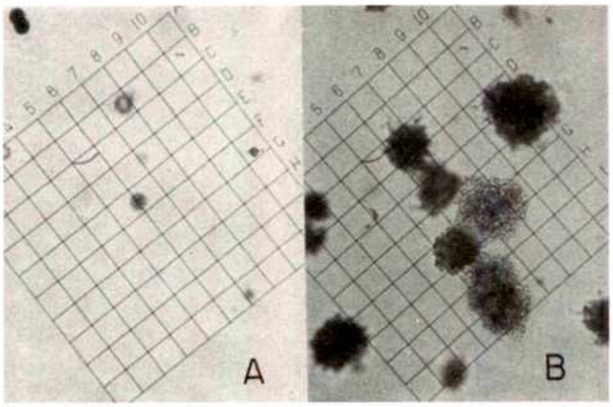

Fig 5. **Colony formation by MML cells in soft agar in the presence of (A) 0.25 μU/mL insulin and (B) 0.25 μU/mL SICRI, in serum-free Dulbecco's modified Eagle's medium supplemented with human transferrin (5 mg/L) and selenous acid (25 μg/L). (Original magnification × 400, current magnification × 220).**

By control experiments, we excluded possibilities of falsely positive SICRI measurements which could have arisen by proteolysis of ^{125}I-insulin and by the presence of other mitogens in SICRI preparations. Parallelity of SICRI concentration and mitogenic potency in affinity-purified SICRI samples is in line with this notion.

The antiinsulin sera employed in our experiments were obtained by immunization of guinea pigs with pure porcine insulin. Antibodies immobilized on agarose gels were previously affinity-purified themselves on an insulin-agarose column. In view of the apparent lack of interference of proinsulin and insulin in the RIA procedures for insulinlike growth factors I and II (IGF I and II),[13] identity of these growth factors and SICRI is not very probable. However, IGF I stimulated growth of cultivated MML cells in a dose-dependent manner up to the concentration of 25 ng/mL (S. Vuk-Pavlovič, unpublished data).

From gel-permeation chromatography data obtained with a Sepharose 6B column under nondenaturing conditions (Fig 6), we calculated the M_r value of native SICRI to be 120,000. Similar values were reported for SICRI in sera of non-Hodgkin's lymphoma patients[3] and in serum-free media cultivated by murine melanoma B16.[16] However, we were not able to assess the M_r value of SICRI in 1 mol/L acetic acid due to our failure to detect any insulinlike material after freeze-drying and reconstitution of chromatographic fractions.

We demonstrate that murine myeloid leukemia in RF mice is accompanied by an increase of SICRI in the whole cell homogenate and circulation. This increase does not affect glucose levels in circulation. Cells of this tumor are serum-independent in culture and secrete SICRI in the medium. Moreover, we conclude that SICRI stimulates growth of SICRI-secreting cells because antiinsulin serum interferes with DNA synthesis dependent on cell density and because affinity-purified SICRI promotes cell growth. Thus, in MML cells, all the elements necessary for establishment and maintenance of autocrine stimulation are present. However, the different extent of stimulation of DNA synthesis by purified SICRI and conditioned IMDM reveals that MML cells produce other growth factors and are stimulated by them.

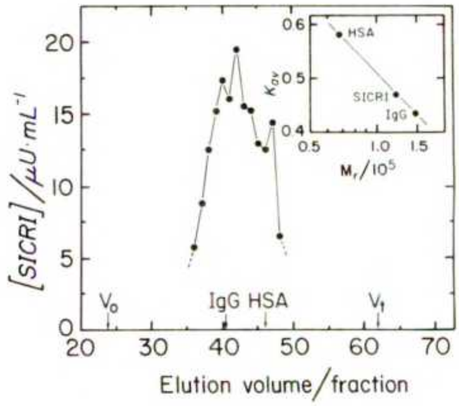

Fig 6. **Molecular sieving chromatography of SICRI on a Separose 6B 0.9 × 50 cm column developed with phosphate-buffered saline containing 0.3 mg/mL bovine serum albumin at a flow rate of 10 mL · cm^{-2} · hr^{-1}. The column was calibrated with blue dextran (V_o, void volume), human immunoglobin G (IgG), human serum albumin (HSA), and potassium ferricyanide (V_t, total volume). Inset: Plot of K_{av} [$=(V_e - V_o)/(V_t - V_o)$ where V_e denotes the elution volume], v log apparent relative molecular mass (M_r) of HSA, SICRI, and IgG.**

Our results show that tumors can produce and secrete substances related to insulin and that these products can serve as tumor growth regulators. These findings suggest an analogy with the expression and role of insulin and related factors in prenatal life,[14] inasmuch as similarities between endocrine aspects of cancer and embryology exist. Also, origins and effects of tumor-produced insulin-related substances seem to mirror other ectopically produced growth factors in tumors.[15]

The Chemokinetic Response of Human Neutrophils

By Thomas H. Howard

A computer-assisted single cell assay that allows quantification of the locomotive behavior of individual cells and a flow-through system that allows study of response of individual cells to stimulation were utilized to study the chemokinetic response of neutrophils. The range of basal mean rate of locomotion (mROL) and chemokinetic response to 10^{-9} mol/L formylmethionyl leucyl phenylalanine (fMLP) was determined for neutrophils of eight normal adults. The basal mROL was 8.2 ± 1.5 um/min and 6.2 ± 1.0 um/min; the rate after 10^{-9} mol/L fMLP was 12.1 ± 2.1 and 9.5 ± 1.8 um/min in 2.0 g% and 0.05 g% HSA, respectively. The mean increase in ROL for neutrophils was 50%. Assay with the flow-through system shows that the chemokinetic response—increase in mROL of a population of neutrophils in response to 10^{-9} mol/L—is due to an increase in ROL when cells are actively moving and not due to a decrease in the amount of time the cell spends inactive. Studies of individual cells within the populations show that chemokinetic response to 10^{-9} mol/L fMLP is highly variable. The majority of cells (77%) respond with an increase in ROL; the minority (23%) are nonresponders that characteristically move at ROL $\geq$ 14 um/min prior to stimulation and do not change ROL or exhibit a net decline in ROL in response to 10^{-9} mol/L fMLP. The dose response of a population of neutrophils and of individual neutrophils to serial addition of 10^{-10} to 10^{-6} mol/L fMLP shows that the fMLP dose dependence for maximal chemokinetic response is highly variable among individual cells. Seventeen percent of cells do not respond to any fMLP concentration; 25% of neutrophils exhibit maximal response to 10^{-10} mol/L fMLP, while 50% and 25% of cells showed peak chemokinetic response to 10^{-9} mol/L and $\geq 10^{-8}$ mol/L fMLP, respectively. These studies document the variability in the locomotive responses of peripheral blood neutrophils. Understanding the causes of variability in the chemokinetic responsiveness of individual neutrophils may improve our understanding of how the cellular inflammatory response in man can be modulated.

© 1986 by Grune & Stratton, Inc.

THE original descriptions of neutrophil locomotion by Sabin,[1] McCutcheon,[2] and Debruyn[3] utilized methods that quantified the locomotive behavior of individual cells. After the early 1950s the Boyden chamber[4] and the chemotactic assay under agarose[5] replaced these single cell methods. The Boyden chamber and agarose assay are less tedious and more readily controlled than single cell methods; however, these new techniques yield less information about the locomotive behavior of neutrophils than do single cell techniques. For example, without major modifications[6] the Boyden chamber and the assay under agarose cannot (A) measure the actual rate of movement of cells; (B) recognize subpopulations of cells that differ in locomotive behavior; or (C) clearly segregate the orientational response and the rate response (chemokinesis)[7] of neutrophils to a chemotactic factor.

These limitations of the Boyden chamber and the agarose assay prompted a return to single cell assays[7–14] to investigate the locomotive behavior of neutrophils. Single cell studies have yielded important information on the range of rates of locomotion for neutrophils,[9,11,13] quantitative description of the irregularity of locomotion,[9,10,12,14] information on the turning behavior of neutrophils,[9,11,15] and allowed analysis of the ability of neutrophils to orient in gradients of chemotactic factor.[7] However, a careful study of the chemokinetic response of neutrophils and the variability in the chemokinetic responsiveness of individual neutrophils has not been reported. For this reason we developed a single cell method that is reproducible and readily controlled.[8] We paired the single cell assay with a flow-through system that allows quantification of the locomotive behavior of the same cells before and after addition of a chemotactic factor and we applied the assay to quantitatively describe the chemokinetic response of neutrophils to formylmethionyl leucyl phenylalanine (fMLP).

MATERIALS AND METHODS

Neutrophils were prepared by the method of Boyum[16] on Ficoll-Hypaque gradients. Resultant preparations were >98% granulocytes with 95% to 96% neutrophils and 4% to 5% eosinophils. The cells were suspended in HEPES/Hanks Balanced Salt Solution (H/HBSSG) (25 mmol/L HEPES, 50 mmol/L Phosphate, 150 mmol/L NaCl, 4 mmol/L KCl, 1 mmol/L MgCl, 1 mmol/L $CaCl^2$, pH 7.15) with 150 mg% glucose and delipidated human serum albumin (SIGMA) as noted. The fMLP (SIGMA) was dissolved in DMSO Equipment utilized in the single cell assay includes the Dvorak-Stotler tissue culture chamber (Nicholson Precision, Bethesda, Md); infrared incubator (Opti-Quip, Highland Mills, NY); telethermometer and banjo probe (YSI, Yellow Springs, Ohio); Leitz Dialux 20 Microscope with 16X bright field objective; Ikegami vidicon videocamera, FORMA time-date generator; Panasonic NV-8030 time lapse videotape recorder; Ikegami videomonitor; and GP60 Sonic digitizer (Science Accessories Co, Norwalk, Conn). The remainder of the details of the assay are given in the text.

Description of single cell assay. Neutrophils at 4 °C are injected into a tissue culture chamber that is servo-linked to an infrared incubator via a heat-sensitive gold probe tapped into the chamber frame The visualization chamber is formed by two coverslips that are 13 mm apart. The temperature of the lower coverslip—the coverslip to which cells are attached—was monitored with a banjo probe sealed to that coverslip and linked to a telethermometer

Cells were injected into the chamber, the chamber was placed on a microscope stage, warmed to 37 °C (coverslip temperature), and allowed to equilibrate at 37 °C for 10 minutes. Using a videocamera, the cells were visualized as 3 to 4 mm black dots on a videomonitor

and were time-lapse videorecorded at 18 times real time for the specified periods of observation.

Following videorecording, the paths taken by the cells were tracked onto plastic transparencies as previously described.[9] The initial position of each cell was marked; the videorecording was advanced a specified period of time, the position of each cell was again marked; and the process was repeated until the desired period of observation had elapsed. In each case, the elapsed time between observations and total time of observation is indicated in Figure legends.

The transparency was placed on the digitizing board of a sonic digitizer/microprocessor and the Cartesian coordinates of each cell at each time of observation were entered into a computer file as a series of six digits following a cell identifier. The working file was entered into an interactive program that allows scaling and feature selection. The program computes the rate of locomotion (ROL) of each cell (ROL = distance travelled/total time observed); the active rate of locomotion (aROL = distance travelled/total time minus time inactive); and the number of 0.5 minute inactive intervals/cell/5 min of observation (0.5 min II/cell/5 min). The terms mean ROL (mROL) and mean active ROL (maROL) are designations used to describe the average locomotive parameter for a population of cells. The terms ROL and aROL are used for individual cells.

Our controls for reproducibility of the single cell assay show that (1) the mROL for a population of cells varies less than 10% during 20 minutes of observation; (2) the mROL of a population of cells from one individual varies <10% from the mean on each of five different days; (3) the mROL of a population is not affected by in vitro age of cells over the range of 3 to 6 hours; (4) the mROL is not affected by cell densities ranging from 45 cells/field to 250 cells/field; (5) the mROL is affected by human serum albumin (HSA) concentration in the H/HBSSG buffer.[9] The HSA (g%) is given in each figure legend.

The flow-through system. For experiments done with the flow-through system, cells at 4 °C are injected into the culture chamber, which is mounted in a plexiglass chamber containing immersion oil. The cells, chamber, and oil are warmed to 37 °C and stabilized for 10 minutes. Cells are videorecorded as noted above during a control period (≥5 minutes), then, during an infusion period, the specified concentration of fMLP or DMSO in H/HBSSG is pumped into the chamber with a Harvard pump (rate 0.220 ml/min) for five minutes; the response period follows fMLP addition. Videorecording continues during the infusion period and during the response period to allow tracking and analysis of the same cell(s) during both the control period and the response period The temperature is maintained at 37 °C during the infusion. The duration of the infusion period and rate of flow is adequate to raise the fMLP concentration to 97% of the influent concentration as documented by infusion of ^{3}[H] fMLP and measurement of cpm from ^{3}[H] fMLP in the effluent. Since flow under these conditions is turbulent (indicated by elution curve and chamber description[11]), no gradient of fMLP exists at any time. This was documented by determining the direction of cell locomotion in the plane of the cover slip The direction of cell locomotion is random; hence, we are studying exclusively the effect of fMLP on rate of locomotion (chemokinesis).

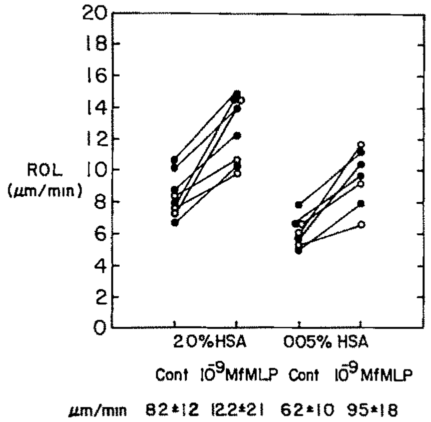

Fig 1. The basal mROL and fMLP-induced chemokinetic response of neutrophils from normal adults. Each point is the mROL of 75 to 100 neutrophils from one subject either male (●) or female (○). The neutrophils were studied in their basal state (cont) or the stimulated state (10^{-9} mol/L fMLP) in the specified concentration of human serum albumin (HSA). Basal and stimulated values for the neutrophils of each subject are connected with a line.

For the serial fMLP dose response, cells are observed in a control period with DMSO (0.1% v/v) present, a five-minute infusion period to 10^{-10} mol/L fMLP follows; then a 5-minute 10^{-10} mol/L fMLP response period; then the infusion of increasing one log steps in fMLP concentrations (10^{-9} – 10^{-6} mol/L) alternated with five-minute response periods.

RESULTS

The chemokinetic response of neutrophils from normal adults. The single cell assay was utilized to determine the basal mROL of normal neutrophils and the chemokinetic effect of fMLP on normal neutrophils. Studies were done in the presence of 0.05 g% and 2.0 g% of HSA. As shown in Fig 1, the basal mROL of neutrophils from five normal males and three normal females is 8.2 ± 1.5 and 6.2 ± 1.0 um/min in 2.0 g% and 0.05 g% HSA, respectively. These values are the mean ± one SD.

Neutrophils from the same normal individuals were also exposed to a uniform concentration of 10^{-9} mol/L fMLP and the chemokinetic response of the neutrophils was determined. As shown in Fig 1, the mROL of neutrophils exposed to 10^{-9} mol/L fMLP is 12.1 ± 2.1 and 9.5 ± 1.8 um/min in the presence of 2.0 g% and 0.05 g% HSA, respectively. The mean percent increase in mROL of neutrophils exposed to 10^{-9} mol/L fMLP was 50% above basal values (range 30% to 70%).

Analysis of the locomotive behavior of neutrophil populations during the chemokinetic response. During four separate trials, 40 to 60 neutrophils were tracked continuously during a five-minute control period, a five-minute infusion period when the concentration of fMLP was raised to 10^{-9} mol/L, and a 5- to 20-minute chemokinetic response period. Quantitative analysis of the continuous tracks yields the mean rate of locomotion (mROL), the mean *active* rate of locomotion (maROL), and the number of 0.5-minute inactive intervals/cell/5 min (#0.5 min II/cell/5 min) for the entire population of cells. Results are shown in Fig 2. The mROL is 9.9 um ± 2.0 um/min during the control period and 17 ± 1.8 um/min during the first five minutes of the response period. This represents a 70% increase in the mROL of the population of neutrophils. The mROL for the population remains elevated for at least 15 minutes after stimulation (15.8 ± 1.8 um/min for the second five minutes, and 16.2 ± 2.2 um/min for the third five minutes of the response period).

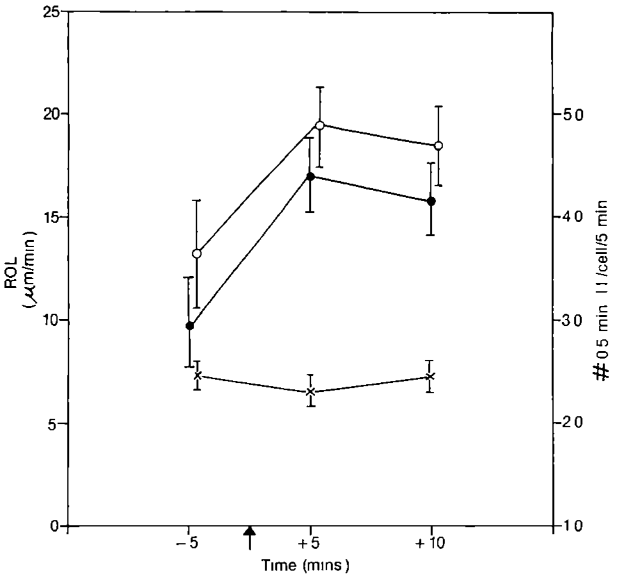

Fig 2. Chemokinetic response of neutrophils to 10^{-9} mol/L fMLP: Locomotive parameters (●—●) mROL (mean rate of locomotion); (○—○) maROL (mean active rate of locomotion) and (x—x) number of 0.5 minute inactive intervals/cell/5 min (#0.5 min I.I./cell/5 min) were measured before (−) and after (+) addition of 10^{-9} mol/L fMLP (↑). Presented is mean ± SD from four trials with 40 to 60 cells studied in each trial. Studies were done in 0.5 g% HSA, cells tracked at 0.5-minute intervals.

In our assay[9] and assays described by others,[10,14] neutrophils are not continuously in motion. Their course is interrupted by periods of inactivity (inactive intervals). Therefore, any increase in the mROL of cells could reflect either a decrease in inactive intervals or an increase in maROL, ie, the rate of locomotion during periods when cells are actively moving. To determine whether the chemokinetic response reflects an increase in maROL, a decrease in inactive intervals, or a combination of both, we determined the maROL and the number of 0.5-minute inactive intervals/cell/5 min before and after fMLP.

An increase in the maROL for the population accompanies the increase in mROL. The maROL for the population is 13.2 ± 2.5 um/min during the control period and 19.2 ± 1.8 um/min during the first five minutes of the response period. The maROL remains elevated for at least 15 minutes and the differential between mROL and maROL is constant (2.4 to 2.6 um/min) during that time. No consistent change in the number of 0.5 min II/5 min was observed (2.0 ± 0.6 before and 1.8 ± 0.6, 2.1 ± 0.6 after fMLP). These results show that the chemokinetic response of a population of neutrophils is due to an increase in the maROL of cells (ie, when cells move they move more rapidly), and is not due to a decrease in the amount of time spent inactive.

The chemokinetic response of individual cells within a population. While mean changes in locomotive parameters (mROL, maROL, #0.5 min II/cell/5 min) for a population of neutrophils clearly describe a chemokinetic response for the population as a whole, the response of individual cells within the population varies widely. This variability is reflected in the plots of the ROL of 25 randomly selected cells as a function of 2.5-minute intervals before and after

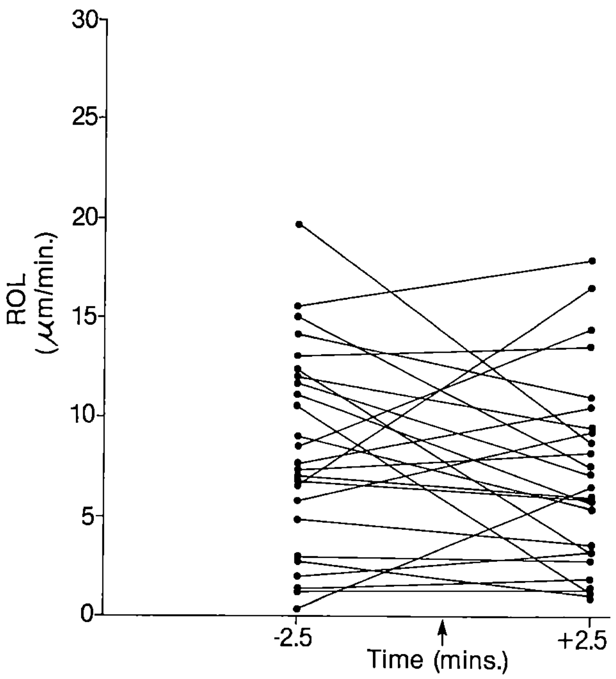

Fig 3. Rate of locomotion (ROL) of individual neutrophils before and after exposure to DMSO: The ROL (um/min) of 25 randomly selected cells before and after exposure to DMSO (0.1% vol/vol), the fMLP solvent is shown. At arrow (↑) DMSO was pumped into the chamber during 5 minutes. X-axis is time before (−) and time after (+) DMSO addition. Cells were studied in 0.5 g% HSA and tracked at 0.5-minute intervals.

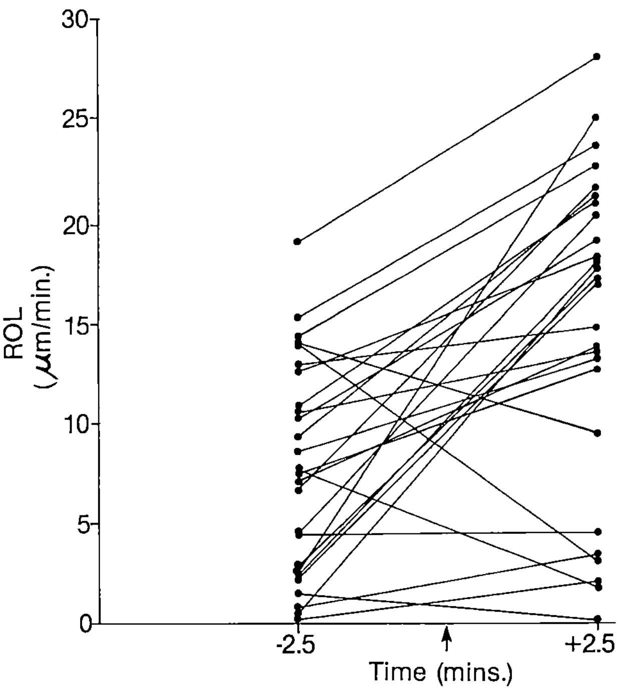

Fig 4. Rate of locomotion (ROL) of individual neutrophils before and after exposure to 10^{-9} mol/L fMLP: The ROL (um/min) of 25 randomly selected cells before and after exposure to 10^{-9} mol/L fMLP is shown. At arrow (↑) 10^{-9} mol/L fMLP was pumped into the chamber during 5 minutes. X-axis is time before (−) and time after (+) fMLP addition. Cells were studied in 0.5 g% HSA and were tracked at 0.5-minute intervals.

exposure to 10^{-9} mol/L fMLP or DMSO in the flow-through system (see Figs 3 and 4). The ROL for individual cells within a population of control- or fMLP-treated cells varies remarkably. For individual fMLP-treated cells it is clear that the trend is toward an increase in ROL; however, some cells exhibit no change in ROL or a definite decrease in ROL after fMLP is introduced Analysis of cells tracked for 10 minutes after fMLP addition show that the most remarkable change in ROL of individual fMLP-stimulated cells is obvious in the 2.5 minutes immediately following completion of fMLP addition and that the cells that respond to fMLP addition with a decrease in ROL never regain their original ROL even after 10 minutes exposure to fMLP; this is not true of control cells. Even if the ROL of an individual control cell decreases, the original or a greater ROL is subsequently observed.

To better define the response of cells to fMLP addition, we plotted the distributions of change in ROL (ΔROL) between the 2.5 minutes prior to and 2.5 minutes following control solvent or fMLP addition. The distributions are plotted both as histograms (number of cells versus ΔROL; Fig 5A) and as cumulative percentage of cells exhibiting equal to or less than a specific ΔROL (ΔROL = ROL 2.5 min following addition minus ROL 2.5 min prior to addition; Fig 5B). The distribution of cells exposed to control solvent is a normal distribution, ie, ~54% responded with no change or a decrease in ROL; 46% responded with an increase in ROL. This is an expected result if the changes in ΔROL are random following control solvent addition. In contrast, the distribution of ΔROL for cells exposed to 10^{-9} mol/L fMLP is markedly skewed toward higher values with 78% of cells exhibiting a gain, ΔROL >0, and 50% responding with a ΔROL of $\geq +5$ um/min. If we use a ΔROL of ≤ 0 um/min to define cells that do not respond to fMLP, then 21% of the 145 cells studied show no response to fMLP stimulation. These cells are nonresponders.

To characterize the locomotive behavior of nonresponders and to compare them to responders, we determined the mean ΔROL of cells as a function of the ROL of cells in the 2.5 minutes prior to 10^{-9} mol/L fMLP addition. As shown in Fig 6, the mean ΔROL for cells that moved <14 um/min prior to fMLP addition was $\geq +5$ um/min; in contrast, the mean ΔROL for cells that moved ≥ 14 um/min prior to fMLP addition was −0.5 um/min. The difference in the means is statistically significant ($P = 0.01$) by t test. This result indicates that the majority of cells with greatest ROL prior to fMLP addition do not exhibit a chemokinetic response to fMLP. In our experimental system it is unusual for cells to exhibit ROLs > 20 um/min before fMLP addition or after control solvent addition. However, after fMLP addition cells commonly attain ROLs > 22 um/min and as high as 33 um/min. Therefore, it is unlikely that cells moving at ≥ 14

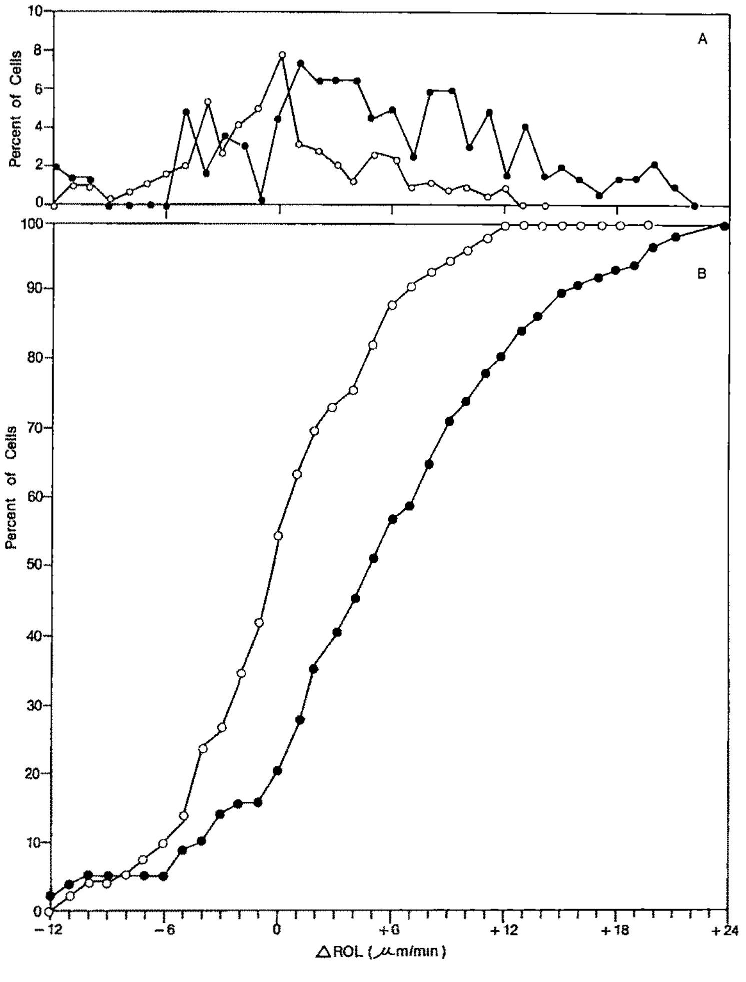

Fig 5. Distribution of ROL for 10^{-9} mol/L fMLP-stimulated neutrophils: (A) Percentage of cells exhibiting a specific change in ROL plotted as a histogram. (B) Same data presented as cumulative percentage of cells exhibiting a specific change in ROL. ΔROL is the difference in ROL of a cell 2.5 minutes prior to and 2.5 minutes following addition of 10^{-8} mol/L fMLP (●—●) or the control solvent DMSO (0.1% v/v) (○—○). The distributions are plotted from 75 cells observed with DMSO and 145 cells with 10^{-8} mol/L fMLP. Cells were studied in 0.5% HSA, tracked at 0.5-minute intervals.

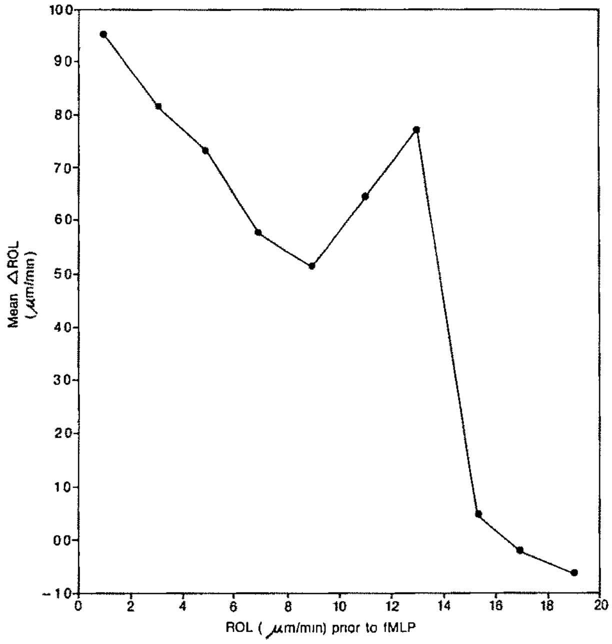

Fig 6. Relationship of mean Δ ROL of 10^{-9} mol/L fMLP-stimulated neutrophils to ROL before stimulation: The mean ΔROL was determined from Σ ΔROL/number of cells with indicated ROL prior to 10^{-9} mol/L fMLP. Y-axis is mean ΔROL; x-axis is ROL in 2.5-minute period prior to fMLP addition. Data reflects analysis of 145 cells.

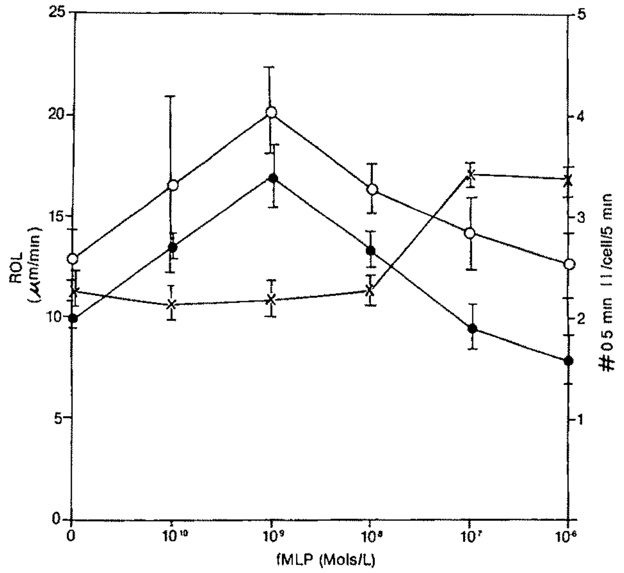

Fig 7. Dose dependence of chemokinetic response to serial addition of fMLP (10^{-10} to 10^{-6} mol/L): Neutrophils were exposed to serial increases in fMLP with 5-minute periods of observation. The (●–●) mROL (mean rate of locomotion), (O—O) maROL (mean active rate of locomotion), and (x—x) number of 0.5 minute inactive intervals/cell/5 min (#0.5 min I.I./cell/5 min) were determined. Cells were studied in 0.5 g% HSA and were tracked at 0.5-minute intervals during the response period. Shown are mean values ± SD for the entire population.

um/min prior to fMLP addition fail to exhibit a chemokinetic response because they are moving at their maximum possible ROL.

Response of locomotive parameters to serial addition of fMLP (10^{-10} to 10^{-6} mol/L). We previously published the dose response for mROL of populations of neutrophils exposed to increasing concentrations of fMLP (10^{-10} to 10^{-6} mol/L).[18] In the previous report, cells were exposed to a single dose of fMLP (10^{-10} mol/L, or 10^{-9} mol/L, or . . . 10^{-6} mol/L) and the mROL of the population was determined. We found that the maximum chemokinetic response occurred at 10^{-8} mol/L fMLP and at concentrations $>10^{-8}$ mol/L the mROL declined to control levels.[18] In the present studies, we used the flow-through system to characterize the dose response of chemokinesis for a population of neutrophils that are serially exposed to incremental increases in fMLP (10^{-10} mol/L and 10^{-9} mol/L and . . . 10^{-6} mol/L). This protocol of serial additions more closely mimics the chemokinesis that would be observed for neutrophils moving in a gradient of chemotactic factor; however, in the experiments presented here no gradient exists.

The maximal mROL for the entire population (Fig 7), ie, the maximal chemokinetic response, occurs with 10^{-9} mol/L fMLP and then mROL declines to control levels at fMLP concentrations $\geq 10^{-8}$ mol/L fMLP. To determine whether the decrease in mROL at $>10^{-8}$ mol/L fMLP was due to an increase in time spent inactive or a decrease in ROL when cells are actively moving, we determined the number of inactive intervals and the maROL of cells as a function of fMLP dose. With serial exposures to fMLP $\leq 10^{-8}$ mol/L the mean number of 0.5 min II/cell/5 min remains constant, the maROL is increased and the difference in maROL and mROL (maROL—mROL) remains constant. These results verify the early studies with 10^{-9} mol/L fMLP alone, ie, the neutrophils increase their mROL because they move faster when they move and not because they spend less time inactive. At fMLP concentrations $>10^{-8}$ mol/L fMLP, the mean number of inactive intervals increases to 3.3/cell/5.0 min, the maROL (13.0 um/min for 10^{-6} mol/L fMLP; 13.0 um/min for control) remains elevated while the mROL drops slightly below control levels (9.0 um/min for 10^{-6} mol/L fMLP; 10.0 um/min control) and the difference between maROL and mROL increases (3.7 to 4.6 um/min at $\geq 10^{-7}$ mol/L; 2.6 to 3.1 um/min at $<10^{-8}$ mol/L). These results indicate that at $>10^{-8}$ mol/L fMLP, the mROL of cells decreases both because the cells spend more time inactive and because they move at slower rates when active. However, the major change is an increase in time inactive.

Figure 8 presents the distribution curves for the maximal ROL observed for individual cells as a function of fMLP concentration. Seventeen percent of cells do not respond with an increase in ROL regardless of fMLP concentration, ie, these cells are nonresponders regardless of fMLP dose. The data show that for cells that exhibit a chemokinetic response to fMLP, the majority of the cells exhibit a maximal chemokinetic response at 10^{-9} mol/L fMLP, and the remaining cells are normally distributed around this value, ie, 25% with maximal ROL at 10^{-10} mol/L fMLP and 25% at $\geq 10^{-8}$ mol/L fMLP.

DISCUSSION

We utilized methods that allow the study of individual neutrophils and populations of neutrophils in order to quantitatively describe the fMLP-induced chemokinetic response

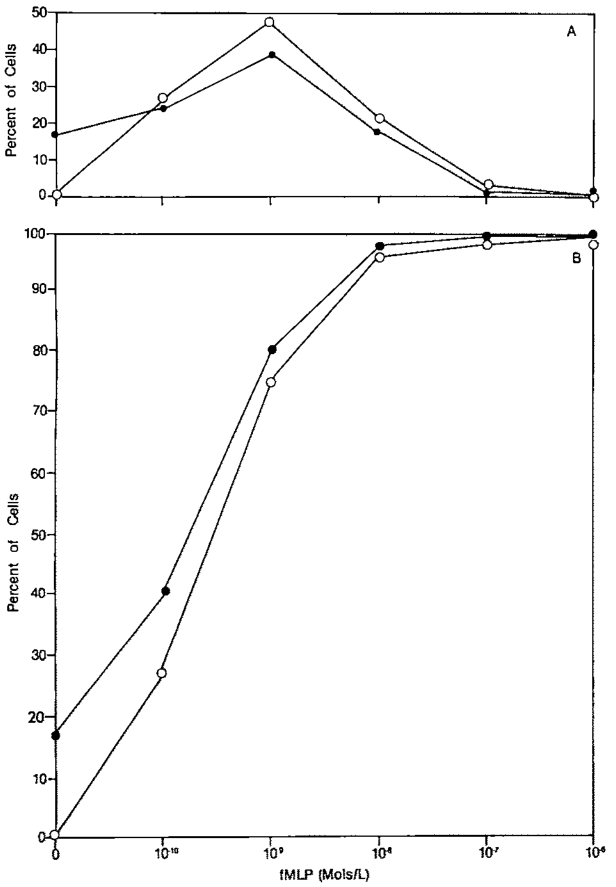

Fig 8. Dose dependency of maximal chemokinetic response of neutrophils: (A) Percentage of cells exhibiting maximal ROL as a function of fMLP dose. (B) Same data presented as cumulative percentage of cells exhibiting maximal ROL as a function of fMLP dose. Data for all cells (●——●) and data for responders (○——○) only are shown. ROL was determined for cells in 0.5 g% HSA, tracked at 0.5-minute intervals for 5 minutes.

of these cells. We investigated the variability in chemokinetic response among adult donors and used a flow-through system (1) to analyze the changes in active ROL and inactive intervals during the chemokinetic response of a population of cells; (2) to describe the variability in chemokinetic response among individual neutrophils in a population; and (3) to analyze the fMLP dose dependency of the chemokinetic response for a population of cells exposed to serial additions of fMLP. Our studies show that chemokinetic responsiveness of ficoll-hypaque purified neutrophils from normal adults is surprisingly constant, and 10^{-9} mol/L fMLP causes a 50% increase in the ROL of neutrophils from normal adults. The basal ROL of neutrophils depends heavily upon HSA concentration in the assay milieu[8]; however, the reproducibility of the basal mROL for a population of neutrophils from normal individuals is excellent.

To characterize the chemokinetic response of neutrophils to fMLP we linked the single cell assay to a flow-through system that allows (1) observation of the same neutrophils in a control and a response period, and (2) quantitative description of the locomotive behavior of a population of neutrophils and the individual cells that constitute the population. Previous studies have shown that neutrophils are not continuously in motion.[9,10,14] Their course of locomotion is interrupted by periods of inactivity as previously documented by Senda,[10] Ramsey,[14] and Howard.[9] Therefore, a neutrophil may increase its ROL in response to fMLP by increasing the rate of cell movement during periods when the cell is moving, by decreasing the amount of time the cell spends inactive, or a combination of the two. Conversely, a decrease in ROL in response to fMLP may be caused by an increase in inactive periods, a decrease in ROL when the cell is moving, or a combination of the two. We learned that the chemokinetic response of a population of neutrophils to 10^{-9} mol/L fMLP results from an increase in the active rate of locomotion of cells, ie, the cells move more rapidly when they are moving. The chemokinetic response to 10^{-9} mol/L fMLP does not reflect a decrease in the amount of time the cell spends inactive.

Also, we defined the fMLP dose dependency for the chemokinetic response of neutrophils exposed to serial increases in fMLP concentration (10^{-10} to 10^{-6} mol/L). The maximal mROL for responsive cells occurs at 10^{-9} mol/L fMLP and, as noted above, that increase in mROL reflects an increase in aROL, not a decrease in time spent inactive. In contrast, at fMLP concentrations $\geq 10^{-8}$ mol/L, the mROL decreased toward control values. This decrease is due to an increase in time inactive as well as a decrease in maROL; however, the increase in time inactive is the major change observed.

Examination of the chemokinetic response of individual cells reveals several points. First, the response of individual cells is highly variable. In fact, 17% to 21% of neutrophils within a population do not exhibit a chemokinetic response to 10^{-9} mol/L fMLP or any other concentration of fMLP. The most obvious locomotive characteristic of the nonresponsive cells is a rapid ROL ($\geq$14 um/min) prior to fMLP addition. The variability in chemokinetic response is consistent with heterogeneity of neutrophil function previously reported by our lab[9] and others.[9,19]

In addition to documenting the utility of single cell studies and quantitatively describing the chemokinetic response of neutrophils to fMLP, these studies yield information about how neutrophils change their rate of movement. The studies show that the neutrophil can alter its ROL either by changing its ROL when it is moving (aROL) or by changing the amount of time inactive as shown with cells exposed, by serial addition, to $\geq 10^{-7}$ mol/L fMLP. These observations heighten the potential importance of inactive intervals and raise questions about why they occur. We know the inactive intervals do not occur only at points where cells are executing acute turns.[9] Do the inactive periods represent a time for cytoskeletal reorganization, as probably occurs during sensory adaptation of neutrophils,[20] a period of ATP depletion following a burst of locomotion, or the time required to amass adequate numbers of assymetrically distributed fMLP receptors to allow the cell to advance?[21] Further study is necessary to explain inactive intervals. The clarification of conditions that increase inactive intervals of neutrophils will aid such studies.

Our observation that 21% of neutrophils are nonresponders matches the proportions of peripheral blood neutrophils which have previously been found to be deficient in a variety of cellular responses including chemotaxis.[19] However, no previous study has examined the chemokinetic response alone and none defined a characteristic by which the nonresponders can be identified without modifying the cell by treating with IgG, stimulants, or antibodies.[22,23] Our observation is that prior to fMLP stimulation the nonresponsive minority of cells move at a faster ROL than do responsive cells.

Finally, the data on fMLP dose dependence to serial addition of fMLP is of interest. First, compared to previous studies of fMLP dose dependency of chemokinesis, which were done with single additions of 10^{-10} mol/L or 10^{-9} mol/L or 10^{-6} mol/L fMLP to a single population of cells, the fMLP concentration that yields peak chemokinetic response is different.[18] With single addition the peak chemokinetic response occurred at 10^{-8} mol/L fMLP, while with serial addition peak response is observed at 10^{-9} mol/L fMLP. Therefore, the protocol used for fMLP addition affects the dose dependency of the chemokinetic response.

Serial addition of fMLP in the flow-through system demonstrates that variability in chemokinetic responsiveness among peripheral blood neutrophils is not limited to responders and nonresponders. Variability also occurs among responders with respect to optimal fMLP dose for maximal chemokinetic response. Twenty-seven percent of responsive neutrophils exhibit maximal chemokinetic response at 10^{-10} mol/L fMLP, and 25% require fMLP concentrations $\geq 10^{-8}$ mol/L or 10^{-7} mol/L, while the majority, 48%, respond to 10^{-9} mol/L fMLP. Even though the peak responsiveness is normally distributed around a mean of 10^{-9} mol/L, marked shifts in the relative proportions of responders and nonresponders or variations in the sensitivity of responders to stimulant may modify the kinetics of the cellular inflammatory response in vivo and render the host more or less susceptible to bacterial infection. Further studies are necessary to examine the relevance of alterations in the percentage of nonresponders and the sensitivity of responders to development of infection in man.

Platelet Storage Pool Deficiency in Pigs

By Todd M. Daniels, David N. Fass, James G. White, and E. J. Walter Bowie

We report a new bleeding disease—storage pool deficiency (SPD) of platelets—in pigs from the Mayo swine colony of homozygous von Willebrand's disease (vWD) and of heterozygous carriers of vWD. Levels of factor VIII, von Willebrand factor antigen (vWF:Ag), and ristocetin cofactor (RCof) were similar in the vWD carriers and SPD pigs. The latter pigs, however, had bleeding times of 15 minutes or more and were severe bleeders, in contrast to clinically normal vWD carriers. Platelet aggregation in response to collagen was reduced in most SPD pigs. Total platelet content of ADP, ATP, and serotonin was less than that of normal pigs. While the initial uptake of ^{14}C-labeled serotonin into platelets was similar in SPD and normal pigs, retention of serotonin was reduced in platelets of SPD pigs. Transmission electron microscopy showed a large decrease of dense bodies in the platelets of SPD pigs. These findings support a diagnosis of SPD. Genetic analyses suggest an autosomal recessive mode of inheritance. A breeding program is under way to produce pigs affected only at the SPD gene, thus allowing further characterization of SPD and SPD-carrier pigs.

IN 1967, a colony of swine affected by von Willebrand's disease (vWD) was established at the Mayo Clinic research facility from a single boar and three unaffected females.[1] Pigs homozygous at the Willebrand locus are characterized by trace levels of von Willebrand factor antigen (vWF:Ag) (0.025 U/dL) and ristocetin cofactor (RCof) (<3 U/dL), low levels of factor VIII, bleeding time of 15 minutes or more, and a severe bleeding tendency. Heterozygous (vWD carrier) pigs have low mean vWF:Ag and RCof values (26 and 30 U/dL, respectively), normal levels of factor VIII, and no bleeding tendency.[2,3] After several generations, a new bleeding manifestation became apparent. These "variant" pigs were characterized by levels of vWF:Ag, RCof, and factor VIII, similar to those seen in vWD carriers, but had bleeding times of 15 minutes or more and a severe bleeding tendency. Epistaxis, dental bleeding, and parturition were potentially life-threatening occurrences in these "variant" pigs, as in homozygous vWD pigs. Genetic analysis suggests that a new bleeding disorder, like porcine vWD, is transmitted in an autosomal recessive manner.[4]

Studies to characterize this bleeding disorder are reported here.

MATERIALS AND METHODS

Preparation of platelet-rich plasma and gel-filtered platelets. Blood was collected in 0.1 volume of 3.8% trisodium citrate or porcine intestinal mucosal heparin (Organon, West Orange, NJ) to a final concentration of 5 U/mL. Platelet-rich plasma (PRP) was prepared by centrifuging blood at 120 × g for 20 minutes. PRP to be assayed for platelet adenosine diphosphate (ADP), adenosine triphosphate (ATP), and serotonin was centrifuged for 4 minutes at 120 × g twice more to ensure the absence of red blood cells.

Citrated PRP (9 mL) was gel-filtered on a 2.5- by 20-cm 2% agarose column. Modified Tyrode's buffer[5] was used (137 mmol/L NaCl, 2.7 mmol/L KCl, 0.36 mmol/L NaH_2PO_4, 1 mmol/L $MgCl_2$, 5 mmol/L HEPES, 5 mmol/L glucose, 0.38% trisodium citrate, 0.35% bovine serum albumin, pH 7 35), and 4-mL fractions were collected The platelets were pelleted and resuspended in normal, vWD, or storage pool deficiency (SPD) platelet-poor plasma (PPP) to a concentration of 2.5×10^5 platelets/μL.

Platelet aggregation. Aggregations were carried out in a Payton dual-channel aggregometer at 37 °C with continuous stirring at 800 rpm. Fifty microliters of an agonist was added to 450 μL of PRP or resuspended gel-filtered platelets (2.5×10^5 platelets/μL). ADP was used at final concentrations of 20 and 10 μmol/L. Bovine Achilles tendon collagen ("Type V," Sigma, St. Louis, Mo) was diluted in Tyrode's buffer (2 g/dL, Difco, Detroit, Mich) and homogenized intermittently in a Waring blender for 90 minutes at 0 °C. The supernatant was sonicated for 3 seconds before use, and was either used undiluted or mixed with an equal quantity of buffer.

ADP, ATP, and serotonin contents in platelets. Extracts were prepared from 7×10^8 platelets.[6] Lyophilized extracts were dissolved in 80 μL of 7 mmol/L potassium phosphate at pH 7.0 and filtered, and 5 to 20 μL was injected for analysis. Components for high pressure liquid chromatography consisted of a Beckman 450 data system/controller and two 114 M pumps, Waters model 441 UV detector at 254 nm, and a 0.46- by 25-cm anion exchange column (Whatman Partisil 10-SAX). ADP was eluted in 0.1 mol/L potassium phosphate at pH 4.2; ATP was eluted in a linear 0.4 to 0.5 mol/L phosphate gradient (ambient temperature, flow rate 3 mL/min) at 0.05 absorbance unit full scale (AUFS). Run time was 42 minutes. Serotonin was eluted with 0.01 mol/L phosphate at pH 3.1 at 1 mL/min. The 450 controller plotting factors were set at 30,000 for the nucleotides and 200,000 for serotonin. Standards were obtained from Sigma (St. Louis, Mo).

Uptake and retention of ^{14}C-labeled serotonin. A modification of the method of Weiss et al[7] was used. Five microliters of ^{14}C-labeled serotonin creatinine sulfate (Amersham, 55 mCi/mmol, 8 μCi/mL) was incubated in 2.5 mL of citrated PRP (6.25×10^8 platelets) for 15 minutes at 37 °C. Imipramine was then added to a final concentration of 10 μmol/L, and incubation was continued at 37 °C. Aliquots were removed at intervals and centrifuged, and the radioactivity of the supernatant was determined in a liquid scintillation counter (Beckman LS7500).

Transmission electron microscopy. Blood samples extracted by venipuncture were mixed immediately with citrate-citric acid-dextrose, pH 6.5 (93 mmol/L sodium citrate, 70 mmol/L citric acid, and 140 mmol/L dextrose) in a ratio of 9 parts blood to 1 part anticoagulant.[8,9] PRP was separated from whole blood by centrifugation at 100 × g.

Samples were combined with an equal volume of 0.1% glutaraldehyde in White's saline, pH 7.3—a 10% solution of a 1:1 mixture of (1) 2.4 mol/L NaCl, 0.1 mol/L KCl, 46 mmol/L $MgSO_4$, 64 mmol/L $Ca(NO_3)_2 \cdot 4H_2O$, and (2) 0.13 mol/L $NaHCO_3$, 8.4

mmol/L $NaH_2PO_4 \cdot 7H_2O$, 3.8 mmol/L KH_2PO_4, and phenol red (0.1 g/L). After 15 minutes at 37 °C, the samples were sedimented to pellets, and the supernatant was discarded and replaced with 3% glutaraldehyde in the same buffer. Fixation was continued at 24 °C for 60 minutes. The cells were then washed in buffer and combined with 1% osmic acid in barbital acetate buffer (0.02 N HCl, a 20% stock solution containing 0.14 mol/L sodium barbital and 0 145 mol/L sodium acetate, and a 6 8% solution of a stock solution containing 1.7 mol/L NaCl and 18 mmol/L $CaCl_2$) After exposure to the second fixative for 1 hour, the cells were dehydrated in a graded series of alcohol and embedded in an epoxy resin (Epon 812). Contrast of thin sections cut from plastic blocks on an ultramicrotome was enhanced with uranyl acetate and lead citrate. Observations were made with an electron microscope (Philips 301).

Infusion studies Two SPD swine were placed on their backs in wooden cradles and restrained by ropes; pigs lie quietly in this position. One 136-kg pig received 1,400 mL of normal pig cryoprecipitate prepared by the method of Slichter et al.[10] The other SPD pig was infused with 410 mL of normal pig platelet concentrate prepared by plateletphoresis in a cell processor (Haemonetics model 30 blood cell processor). The total platelet content was 10.7 × 10^{11}, which was calculated to result in an increase of 3.0 × 10^8 platelets/mL. Blood was removed at intervals for hemostatic tests, and ear bleeding times were determined.

RESULTS

Aggregation studies. Collagen-induced aggregation in citrated PRP was absent or decreased in 10 of the 11 SPD pigs (Fig 1). The response to collagen of platelets from vWD and vWD-carrier pigs was varied (two of eight vWD pigs and two of six vWD-carrier pigs having absent or decreased collagen-induced aggregation). A likely explanation for this finding is that some vWD-carrier pigs were heterozygous at the SPD gene and the vWD pigs were either homozygous or heterozygous at the SPD gene. A breeding program is under way to breed separate strains of SPD and vWD pigs and to characterize pigs of each of the nine possible genotypes involving the SPD and vWD genes.

Results of studies using resuspended gel-filtered platelets are plotted in Fig 2. The maximal recorder pen deflection was expressed as ΔT. SPD platelets were less responsive to collagen whether resuspended in normal, vWD, or autologous PPP. In contrast, normal platelets aggregated in response to collagen when resuspended in PPP from pigs with SPD.

ADP, ATP, and serotonin contents of platelets. The total content of adenine nucleotides, as well as serotonin, in SPD platelets was less than that of normal pigs (Fig 3). Mean values in SPD pigs studied were 31% for ADP, 34% for ATP, and 23% for serotonin of the mean values in normal pigs. To test whether the low values in SPD pigs were

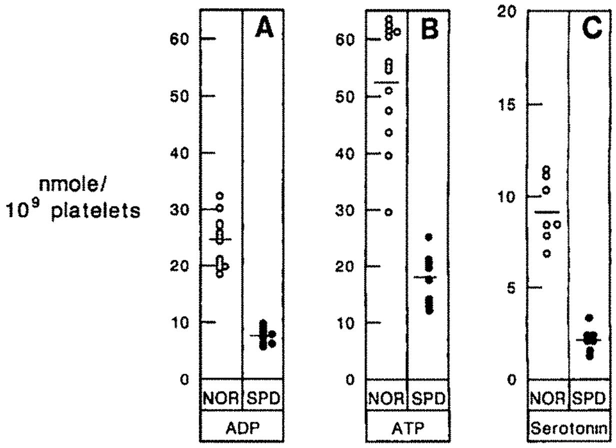

Fig 3. (A) ADP, (B) ATP, and (C) serotonin contents of unrelated normal and SPD pig platelets. Each platelet pellet (7 × 10^8 platelets) was freeze-thawed, extracted twice with 12% trichloroacetic acid, extracted 10 times with diethyl ether, and lyophilized. Samples were dissolved in 80 μL of phosphate buffer, and 5 to 20 μL was injected for analysis by HPLC. Phosphate buffers were used to elute sample components from an analytical anion exchange column, and absorbance at 254 nm was monitored.

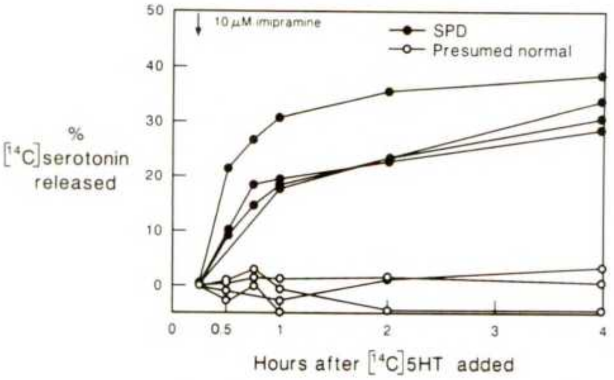

Fig 4. Release of ^{14}C-labeled serotonin from SPD and unrelated normal pig platelets. ^{14}C-labeled serotonin (0.29 µmol/L final concentration) was added to 2.5 mL of citrated PRP (2.5 × 10^8 platelets/mL). After 15 minutes at 37 °C, imipramine was added to a final concentration of 10 µmol/L, and incubation at 37 °C was continued. Aliquots (300 µL) were removed at intervals and centrifuged, and supernatant radioactivity was determined in a liquid scintillation counter.

characteristic of swine in our closed herd, ADP and ATP contents were determined in three vWD pigs and serotonin content was determined in one vWD pig. Pigs with vWD whose platelets aggregated normally in response to collagen were used for these determinations. Mean values were ADP 109.8%, ATP 104.7%, and serotonin 91.8% of the mean values for unrelated normal pigs.

Uptake and retention of ^{14}C-labeled serotonin. Uptake of ^{14}C-labeled serotonin after 15 minutes was similar in the two groups of pigs (normal 76.2%, SPD 70.7%). At 15 minutes, imipramine was added to inhibit the reuptake of any serotonin released by the platelet. Release of ^{14}C-labeled serotonin from SPD platelets was evident 15 minutes after the imipramine was added; and at 4 hours, SPD platelets had released approximately one third of the ^{14}C-labeled serotonin originally taken up (Fig 4). Normal pig platelets retained the amine for 4 hours.

Electron microscopic findings. Thin sections of the platelet preparation from a normal and a SPD pig were examined by transmission electron microscopy. There were 57 dense bodies in thin sections of 125 platelets in the normal pig and 15 dense bodies in the same number of cells from the SPD pig (Fig 5).

Infusion studies. Enough normal porcine cryoprecipitate was infused into a SPD pig to raise the levels of vWF:Ag from 26 to 97 U/dL and of RCof from 29 to 103 U/dL 30 minutes after infusion. The bleeding time remained abnormal (over 15 minutes) through 24 hours (Fig 6). Such an infusion corrects the bleeding time in vWD pigs.[11] Another SPD pig received platelet concentrate from a normal pig, which raised its platelet concentration by a maximum of 2.1 × 10^8 platelets/mL 1 hour after infusion. Bleeding time was shortened and transiently corrected to normal (Fig 6). Increased collagen-induced platelet aggregation was apparent after platelet infusion (Fig 6). Before infusion, the response curve to collagen had a slope of 1.5 and a zero ΔT. (This can occur because SPD platelets undergo a transient change in shape, resulting in a measurable slope; however, ΔT does not exceed zero—the original baseline—in some instances.)

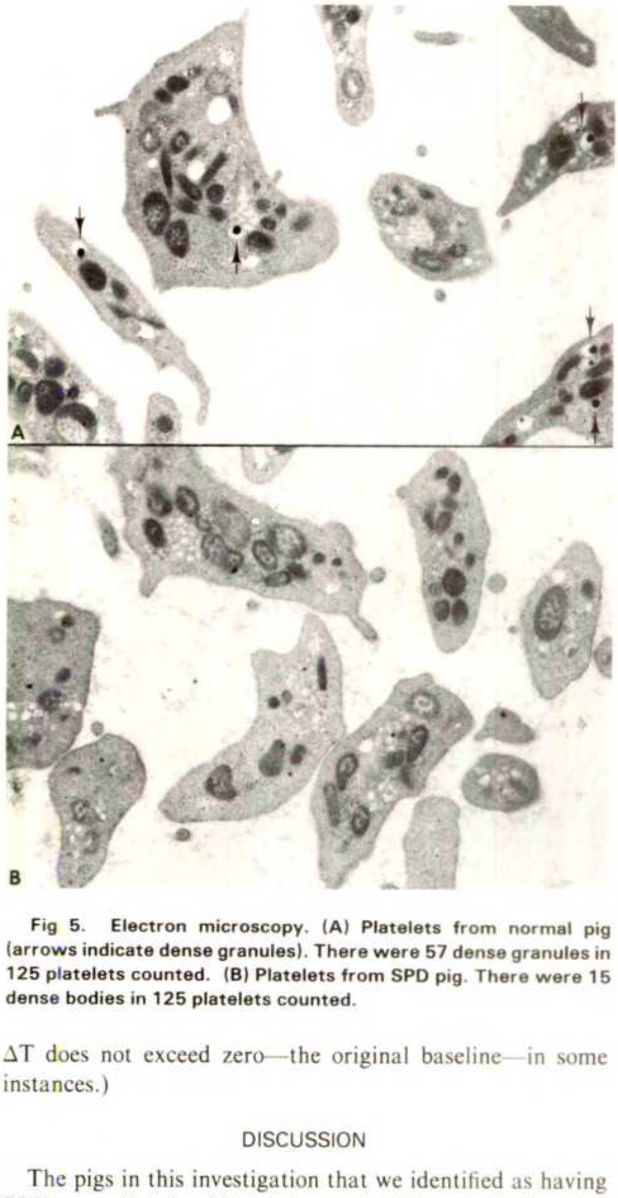

Fig 5. Electron microscopy. (A) Platelets from normal pig (arrows indicate dense granules). There were 57 dense granules in 125 platelets counted. (B) Platelets from SPD pig. There were 15 dense bodies in 125 platelets counted.

DISCUSSION

The pigs in this investigation that we identified as having SPD were all derived from a herd of vWD and vWD-carrier swine. Our studies have shown that the platelets of these SPD pigs have a decreased number of dense granules and decreased amounts of serotonin, ADP, and ATP. Furthermore, platelet retention of serotonin after the addition of imipramine was impaired.

Pigs with homozygous vWD are characterized in part by extremely low vWF:Ag and RCof values (less than 3 U/dL), bleeding times of more than 15 minutes, and a life-threatening bleeding diathesis. Pigs heterozygous for vWD have higher, but not normal, mean levels of vWD-Ag and RCof (26 and 30 U/dL, respectively), normal bleeding times, and no bleeding tendency. Pigs from our herd with SPD have vWF:Ag and RCof levels similar to those in pigs heterozygous for vWD but, in contrast, have prolonged bleeding times—often more than 15 minutes—and a life-threatening bleeding tendency.

The observation that the SPD pigs originated in a vWD herd prompted us to investigate the possibility that they were

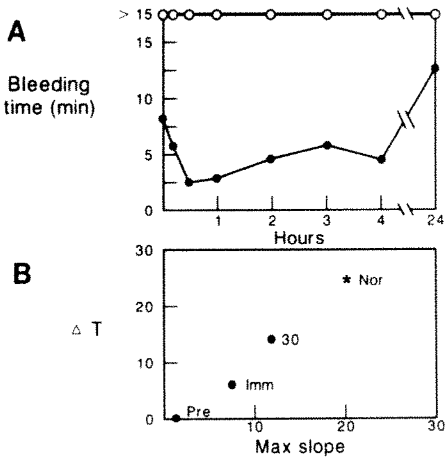

Fig 6. Infusion of cryoprecipitate or platelet concentrate of normal pig into SPD pigs. (A) Solid circles represent bleeding times before and after infusion of 410 mL of platelet concentrate from normal pig. Platelet count increased by a maximum of 2.1×10^8 platelets/mL at 30 minutes after infusion. Open circles represent bleeding times before and after infusion of 1,400 mL of normal porcine cryoprecipitate. FVIII, vWF:Ag, and RCof increased by 37%, 273%, and 255% over preinfusion levels, respectively, 30 minutes after infusion. Each bleeding time is the mean of two determinations per time point per pig. In the pig, mean (± SD) normal bleeding time is 2.2 ± 0.75 minutes and vWD carrier bleeding time is 3.2 ± 1.3 minutes.[4] Time of cessation of initial bleeding was used; "rebleeding," a phenomenon common in SPD pigs, is not indicated in the graph. (B) ΔT *v* maximal slope of collagen-induced platelet aggregation curve before and after infusion of platelet concentrate. Pre, preinfusion; Imm, immediately after infusion; 30, 30 minutes after infusion; and Nor, unrelated normal pig control.

affected by a variant form of vWD similar to that found in humans because they had long bleeding times and mean values of vWF:Ag and RCof of 25 and 35 U/dL, respectively. Examination of the von Willebrand factor multimers, however, revealed no abnormality, and our experience with porcine vWD suggested that the plasma level of von Willebrand factor was not low enough to cause bleeding without some additional abnormality being present. This led us to investigate other causes of the prolonged bleeding time and to the discovery of platelet SPD.

Like vWD, SPD is inherited as a simple autosomal recessive locus segregating independently of the similarly autosomal recessive von Willebrand locus.[4] The vWD pigs in our herd, therefore, are homozygous, heterozygous, or normal at the SPD locus. Those with homozygous SPD display impaired collagen-induced platelet aggregation; all others have normal collagen-induced aggregation and nucleotide content. The vWD carriers also are either heterozygous or normal at the SPD locus. The vWD carriers have normal bleeding times and therefore cannot be homozygous at the SPD locus. Pigs with prolonged bleeding times, low platelet nucleotide content, decreased collagen-induced aggregation, and mean levels of vWF:Ag and RCof of 25 and 35 U/mL, respectively, are SPD pigs that also happen to be carriers of vWD. We have not been able to identify SPD pigs that definitely do not carry vWD. The lower values of vWF:Ag and RCof in normals overlap the higher values in carriers.[3,4]

Because our breeding program was focused on producing vWD and vWD-carrier pigs, it can be expected that most of the SPD pigs identified were carriers of vWD. In fact, pedigree analysis shows that all of the SPD pigs in this study may be carriers of vWD (eg, some SPD pigs were the offspring of one vWD pig, and the others were offspring of vWD carriers). We have initiated a backcross breeding program to produce pigs affected only at the vWD locus or the SPD locus. It will then be possible to determine if the decreased levels of vWF:Ag and RCof are due to heterozygosity at the vWD locus or are linked to the expression of SPD.

Like platelets in the human disease, platelets in porcine SPD show abnormal aggregation with collagen. The secondary response of platelet aggregation to epinephrine and ADP is also abnormal in human SPD. Using our aggregation procedure, however, platelets of normal pigs do not aggregate in response to epinephrine, and there is only primary (reversible) aggregation with ADP. Thus, abnormal collagen-induced aggregation is the only detectable abnormality of porcine platelet aggregation that resembles SPD in humans.

Platelet storage pool deficiency in humans can be categorized on the basis of a decrease of substances stored in the dense granules (SPD or δ-SPD), rarely the α-granules (α-SPD or gray platelet syndrome), or both dense and α-granules ($\alpha\delta$-SPD).[12,13] SPD involving dense granules often accompanies other clinical abnormalities, such as the Chédiak-Higashi syndrome,[14,15] Hermansky-Pudlak syndrome,[16,17] Wiskott-Aldrich syndrome,[18] and thrombocytopenia absent radii syndrome.[19]

SPD has been found in association with the Chédiak-Higashi syndrome in mink,[20] cattle,[21] and cats.[22] Several pigment mutations in mice have been associated with SPD.[23,24] Recently, it has been shown that SPD in fawn-hooded rats[25,26] is a pleiotropic effect of the red-eyed dilution gene.[27]

The only additional abnormality that we have thus far detected in our SPD pigs is reduced vWF:Ag and RCof. We believe that the original breeding strategy would have produced many SPD pigs that were also carriers of vWD, so that pigs produced by the current breeding program and affected only at the SPD gene may have normal levels of vWF:Ag and RCof. If this is true, these pigs may be an animal model for the idiopathic inherited SPD found in humans.[7,12,28,29]

Expression of Normal Myeloid-Associated Antigens by Acute Leukemia Cells

By Patricia A. Dinndorf, Robert G. Andrews, Denis Benjamin, Derry Ridgway, Lawrence Wolff, and Irwin D. Bernstein

Monoclonal antibodies that react with hematopoietic cells and their precursors in a stage and lineage restricted fashion were used in indirect immunofluorescence assays to examine leukemic cells from 105 pediatric age patients. The differentiative states of blasts from 42 patients with acute nonlymphocytic leukemia (ANLL) were defined by these antibodies. When these were compared to their morphologic and histochemical levels of differentiation as defined by the French-American-British (FAB) classification, no direct relationship was found. The reactivity of these antibodies with leukemic cells from 63 patients with acute lymphocytic leukemia (ALL) was also investigated, and the usefulness of these antibodies in distinguishing leukemias of myeloid from those of lymphoid origin was demonstrated.

© 1986 by Grune & Stratton, Inc.

ACUTE nonlymphocytic leukemia (ANLL) is a heterogeneous group of disorders that originates at the level of hematopoietic progenitor cells. ANLL subtypes have classically been categorized according to morphologic and histochemical criteria, which have been more precisely defined in recent years by the French-American-British (FAB) classification.[1] An alternate approach to assess the heterogeneity of ANLL is to use monoclonal antibodies that react with antigens expressed by normal hematopoietic cells and their precursors in a lineage and stage-restricted fashion.

We have used such monoclonal antibodies to examine the differentiative state of ANLL in children.[2,3] Importantly, a comparison of the differentiative state of ANLL cells based on morphologic and histochemical criteria (defined by the FAB classification), with their antigenic phenotype failed to reveal a direct relationship. In addition, we have used these antibodies to examine acute lymphocytic leukemia (ALL) cells, and demonstrated their usefulness in distinguishing leukemias of myeloid versus lymphoid origin.

MATERIALS AND METHODS

Cells Heparinized marrow or peripheral blood obtained at the time of the initial diagnosis or relapse of leukemia was obtained from pediatric patients at Children's Orthopedic Hospital and Medical Center, Seattle, Washington, and at the Doernbecher Children's Hospital, Oregon Health Sciences University, Portland. Samples from children with ANLL were collected beginning in 1973 at the Children's Orthopedic Hospital and Medical Center, and at the University of Oregon beginning in September 1979 when the Children's Cancer Study Group (CCSG) 251 study for the treatment of ANLL was opened. ALL samples were collected beginning in January 1979 with the inception of the CCSG study 191 for the treatment of average and high risk ALL, and from Oregon beginning in May 1983 with the inception of CCSG protocols 104, 105, 106, 107, and 123 for the treatment of children with various risk factors. Cells were separated by Ficoll-Hypaque density centrifugation (density 1.077), suspended in newborn calf serum supplemented with 10% dimethyl sulfoxide (DMSO), and frozen in liquid nitrogen until studied. All samples had greater than 75% malignant blast cells, as determined by examination of Wright stained cytospin preparations of thawed cells at the time of phenotyping, and viability was greater than 75% as assessed by trypan blue dye exclusion.

Monoclonal antibodies. Unfractionated ascites fluids containing monoclonal antibodies were used at dilutions from 1:250 to 1:1,000 in all studies. Antibody T11D7, an isotype identical (IgM) murine monoclonal antibody of irrelevant specificity (antimouse Thy 1.1; kindly provided by Dr E Clark, University of Washington, Seattle) served as a negative control. Production and characterization of monoclonal antibodies 1G10, 5F1, L4F3, and T5A7 has been described elsewhere[2-6] and their reactivities are summarized in Table 1. Monoclonal antibodies to lymphoid-associated antigens used to characterize ALL included CALLA (J-5 provided by Dr John Pesando or BA-3 provided by Dr John Kersey)[10] and T-cell antibodies (9.6, 10.2, 12 1, and 38.1 provided by Dr John Hansen and 3A1 provided by Dr Barton Haynes).[11]

Immunofluorescent studies Cells were incubated with monoclonal antibody diluted in Minimal Essential Medium (MEM) supplemented with 5% newborn calf serum and 2% human AB serum (Irvine Scientific, Santa Ana, Calif) for 30 minutes, washed, and then incubated with a 1:40 dilution of an affinity-purified fluorescein-conjugated goat antimouse IgM antiserum (Litton Bionetics, Kensington, Md) as previously described[2] As a negative control, cells also were stained with the isotype identical antibody, T11D7 (antimouse Thy 1.1). Stained cells were analyzed by flow microfluorimetry using a FACS 440 (Becton Dickinson, Oxnard, Calif). A total of 4,000 cells was analyzed for each antibody. Antibody staining of cells was considered positive if more than 25% of cells exhibited fluorescence intensity greater than 95% of the cells stained with the negative control antibody. Twenty five percent was used as the cutoff because all samples analyzed contained no more than 25% normal contaminating cells and, therefore, at this level at least some of the reactivity was with leukemic cells. In the case of L4F3, if there was a homogeneous shift of the median fluorescence intensity (peak) to greater than 1.5 times that of cells stained with T11D7, cells were also considered positive. In cases where there was a homogeneous shift, 100% of the cells were considered to express the antigen. This conclusion was confirmed by demonstrating that for 23 leukemic samples that had been determined to express L4F3 by these criteria, all cells were susceptible to complement-mediated lysis by L4F3 in a ^{51}Cr release assay. The complement-mediated cytotoxicity assay has been previously described.[2]

Cytochemical studies and FAB classification. The diagnosis of ALL or ANLL was made at the institution of origin based on standard morphological and cytochemical criteria. Leukemia classified as ALL was not peroxidase, sudan black, or chloracetate esterase positive; most were PAS positive. Marrows of patients

diagnosed as having ANLL were reviewed by two investigators (DB, PAD) specifically examining cytochemical stains including Wright-Giemsa, periodic acid Schiff (PAS), peroxidase, sudan black, NSE (alpha naphthyl butyrate), chloracetate esterase, and acid phosphatase. These cases were classified according to the FAB schema.[1] That is, cases that were peroxidase or sudan black positive were categorized as M1, M2, or M3, depending on the degree of differentiation. Cases that were peroxidase (sudan black) and NSE positive were classified as M4. Specimens that were NSE positive only were classified as M5. Leukemia was classified as M6 or erythroleukemia based on the morphologic appearance of cells and PAS reactivity.

Terminal deoxynucleotidyl transferase (TdT) staining. TdT determinations were made on cryopreserved leukemic cells of the patients whose cells expressed myeloid antigens. Cytospin preparations were fixed in absolute methanol at 4 °C for 30 minutes, then incubated with rabbit anti-TdT serum, followed by FITC conjugated goat $F(ab')_2$ fragments specific for rabbit IgG (Bethesda Research Laboratories, Gaithersburg, Md).

RESULTS

Reactivity of monoclonal antibodies with ANLL cells. The reactivity of monoclonal antibodies 1G10, 5F1, T5A7, and L4F3 with leukemic samples from 42 pediatric patients with ANLL was examined by indirect immunofluorescence. The specificities of these antibodies and antibodies that appear to recognize the same determinants are summarized in Table 1. In brief, two of these antibodies discriminate between granulocytic and monocytic cells. 1G10, an X-hapten reactive antibody (CD15),* reacts with cells at all stages of granulocytic differentiation to the promyelocyte level, but only with a portion of myeloblasts and granulocyte-macrophage progenitors (CFU-GM). In contrast, antibody 5F1 reacts with monocytes, platelets, megakaryocytes, nucleated erythrocytes, and erythroid colony-forming cells (CFU-E), but not with granulocytic cells.

The other two antibodies, L4F3 and T5A7, react with antigens expressed at maximal concentrations on granulocytic cells at different stages of maturation. Thus, L4F3 reacts most intensely with metamyelocytes, myelocytes, promyelocytes, and a portion of myeloblasts, and virtually all CFU-GM, while the T5A7 antigen (lactosylceramide) is expressed maximally on mature granulocytes, and a minor proportion of Day 7 CFU-GM. Both of these antibodies also react with monocytes. In addition, T5A7 reacts with 20% of PHA-stimulated lymphocytes.

---

*Designation of the 2nd International Workshop on Human Leucocyte Differentiation Antigens.[7]

The results show that 40 of 42 leukemic samples examined reacted with at least one of the antibodies (see Fig 1). 1G10, which predominantly reacts with granulocytes, bound to 55% of the samples tested, while cells from 69% of the samples bound 5F1, the monocyte reactive antibody. Thirty-five specimens (83%) reacted with either one or both of these antibodies. Ninety percent of the samples tested reacted with L4F3, the antibody that binds maximally to immature myeloid cells. Cells from 61% of the samples reacted with T5A7, the antilactosylceramide antibody that binds maximally to mature myeloid cells. Only two specimens (5%) failed to react with any of the antibodies tested.

FAB classification of ANLL cells. For each patient studied, bone marrow aspirates obtained at initial diagnosis were stained with Wright Giemsa, and for peroxidase, sudan black and NSE, and were classified according to the FAB classification for ANLL. Cells from 15 patients were classified as M1 (myeloblast), 4 as M2 (myeloid with maturation), 1 as M3 (promyelocytic) (confirmed by the 15:17 chromosomal translocation), 16 as M4 (myelomonocytic), 4 as M5 (monocytic), and 2 as M6 (erythroblastic). The M5 category was subdivided into 2 cases of M5A (immature) and 2 cases of M5B (differentiated).

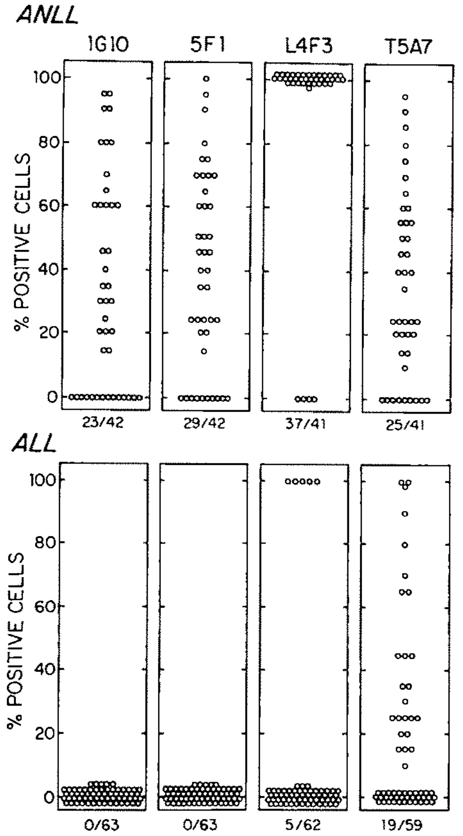

Fig 1. Reactivity of monoclonal antibodies with ANLL and ALL. The reactivity of leukemic cells with monoclonal antibodies was determined for each specimen by indirect immunofluorescent antibody binding and analysis by flow microfluorimetry. For each antibody a specimen was considered positive if ≥25% of cells were reactive. [(No. specimens positive)/No. specimens tested) = (percent of specimens positive)].

Comparison between antigenic phenotype and FAB classification of ANLL cells. The differentiative state of leukemic cells defined according to FAB classification or antigenic phenotype were generally discordant (Table 2). First, most specimens classified as FAB M1 did not react with 1G10 which reacts with most granulocytic elements. This may reflect the immaturity of these cells with respect to granulocytic differentiation. However, leukemic cells which appeared by conventional criteria to have differentiated further along the granulocytic pathway, ie, specimens classified as M2 and M3, also failed to react with 1G10 in three of five instances. In contrast, the majority of these cells (M1, M2, and M3) reacted unexpectedly with 5F1, a reaction not seen with normal granulocytes. Also unexpected was the reaction of all leukemias classified as FAB M5 with 1G10. One pattern that did emerge was that specimens classified as FAB M4 tended to react with all the antibodies tested.

The relationship between maturation according to antigenic and morphologic criteria was also evaluated. Since the surface expression of the antigen identified by L4F3 is greatest on the least as compared to the most mature myeloid cells,[3] we determined whether this relationship was also found between leukemic cells classified as less or more differentiated. A comparison of the relative fluorescence intensity of samples stained with L4F3 among the FAB subgroups revealed no obvious relationship between fluorescence intensity and maturation (data not shown). This however may have been a consequence of the small number of more mature (M2, M3, M5b) specimens. A similar lack of a relationship between morphologic and antigenic differentiation was not found for T5A7 which reacts maximally with mature myeloid cells. Seven of 15 leukemias classified as M1 (myeloblast) reacted with T5A7, while only one of five samples that were morphologically more mature and classified as M2 or M3 reacted with T5A7.

Table 2. Reactivity of Monoclonal Antibodies With Subgroups of ANLL

	Antibodies			
FAB/Cytochemistry	1G10	5F1	L4F3	T5A7
M1/peroxidase				
(Immature myeloid)	3/15	10/15	14/15	7/15
M2/peroxidase				
(Myeloid with maturity)	2/4	2/4	2/4	1/4
M3/peroxidase				
(Promyelocytic)	0/1	0/1	ND	0/1
M4/peroxidase, NSE				
(Myelomonocytic)	14/16	12/16	16/16	13/16
M5A/NSE				
(Monocytic, immature)	2/2	1/2	1/2	2/2
M5B				
(Monocytic, mature)	2/2	2/2	2/2	1/2
M6				
(Erythroblastic)	0/2	2/2	2/2	1/1

Number of samples reacting with antibody over number of samples tested of each FAB subclassification.

Comparison between peripheral blood and bone marrow phenotype of ANLL cells. Because peripheral blood rather than marrow cells was often evaluated, we compared antigenic phenotypes of leukemic cells obtained from the peripheral blood and marrow in eight patients in whom both types of specimens were available. These paired samples were obtained at the same time in the patient's disease, that is, at initial diagnosis or at the time of a subsequent relapse. Importantly, the proportion of leukemic cells reactive with the antibodies 1G10 and 5F1 as determined in peripheral blood or bone marrow was similar (within 15%). In all instances, except for one patient each in the case of antibody 5F1, 1G10, and T5A7, the positive or negative nature of the bone marrow or peripheral blood sample was concordant.

In studies with T5A7, a slightly greater percent (<15% except in one instance where it was 25%) of leukemia cells were positive in the peripheral blood as compared to the marrow in almost every case. Again these differences altered the interpretation of T5A7 reactivity in only one case. This may have been the consequence of a greater number of normal mature cells contaminating the peripheral blood specimens or a higher proportion of the circulating malignant cells as compared to those in the marrow which express lactosylceramide in the periphery. The former, however, is unlikely in the absence of a consistently greater activity of 1G10 or 5F1 with peripheral blood granulocytes or monocytes, respectively, that might have been present in the peripheral blood specimens.

Expression of myeloid-associated antigens by ALL cells. Leukemic samples from 63 pediatric patients with ALL were also examined for reactivity with the anti myeloid monoclonal antibodies (see Fig 1). These patients were diagnosed as having ALL based on morphological and cytochemical criteria. The reactivity of these cells with lymphoid-associated monoclonal antibodies was reported in a previous study[12] and is summarized in Table 3. None of the specimens reacted with either antibody 1G10 or 5F1. Lymphoblasts from 5 of 62 samples tested reacted with L4F3. Of the five, three expressed CALLA and the other two lacked both CALLA and T-cell antigens. Clinically, these five patients all underwent remission induction successfully and remain in complete continual remission 38, 53, 54, 59, and 68 months from initial diagnosis.

Table 3. Reactivity of Monoclonal Antibodies With Subgroups of ALL

Serologically Defined Subgroups	Myeloid Antibodies			
	1G10	5F1	L4F3	T5A7
T+* CALLA + or −	0/16	0/16	0/15	8/15
T− CALLA +	0/41	0/41	3/41	7/38
T− CALLA −	0/6	0/6	2/6	4/6

Indirect immunofluorescent reactivity of monoclonal antibodies with malignant cells by FACS analysis. For each antibody a specimen was considered positive if ≥25% of cells were reactive. Results are reported as (number of samples positive)/(number of samples tested).

*Specimens were tested with either antibodies 9.6 and 10.2 separately or with a cocktail consisting of 9.6, 10.2, 12.1, 3A1, and 38.1.

Cells from six of the patients with ALL did not express the T-cell–associated antigens that were evaluated or CALLA. Cells from two of these patients reacted with L4F3 as mentioned above, and one reacted with both L4F3 and T5A7. Of the three cases in this group that reacted only with T5A7, two were infants who died within one year of diagnosis, an outcome typical of this disease in infants. The third remains in continuous remission at 31 months. The patient whose cells failed to react with any of the antibodies tested also remains in initial remission at 23 months.

The antigen defined by T5A7, lactosylceramide, was expressed on a significant proportion of lymphoblasts in 19 of 59 specimens tested. Eight of 15 T-cell leukemias tested expressed this antigen. This is not surprising, since T5A7 is known to react with a proportion of PHA-stimulated peripheral blood T cells.[3] Four of eight patients with T-cell ALL whose blasts reacted with T5A7 remain in complete continual remission from 25 to 54 months from initial diagnosis while three of seven patients whose cells did not react with T5A7 are alive 26 to 61 months from initial diagnosis. Cells of seven of 38 CALLA positive cases were reactive with T5A7. However, there appeared to be no difference in this small series in the survival of patients whose cells did and did not react with T5A7 (data not shown).

Terminal deoxynucleotidyl transferase (TdT) determinations were done on all but two of the ALL specimens which stained with one or more antimyeloid antibodies. Of the five that were L4F3 positive, four were tested for TdT expression, and all were positive; and of the 19 specimens that reacted with T5A7, 18 were tested and all were positive.

DISCUSSION

ANLL is generally categorized according to morphological and histochemical criteria set forth by the FAB group and is based on expression of characteristics normally associated with granulocytic, monocytic, or erthrocytic cells.[1] This classification has largely failed to identify groups of prognostic importance. This system relies on subjective criteria and concordance between hematopathologists is not high. We have directly compared the assignment of cell lineage defined by the FAB system to that defined by reactivity with antimyeloid monoclonal antibodies. In the present study, a comparison of differentiative states of leukemic cells defined by the presence of histochemical markers versus that defined by the expression of myeloid-associated antigens failed to demonstrate a direct relationship between these two. Specifically, an association between the presence of peroxidase and the expression of a granulocyte-associated antigen (1G10) was not found. Nor did we observe a direct correlation between the presence of NSE and the expression of a monocyte-associated antigen (5F1).

This failure to define a relationship between lineage assignments defined by these two methods is not surprising since each of these approaches examines the expression of only a few of the gene products normally displayed by myeloid cells of specific lineages or at specific stages of maturation. Thus, in the FAB system only cytoplasmic peroxidase and NSE, which are selectively expressed during normal granulocytic or monocytic differentiation, respectively, are evaluated. Examination of the expression of cell surface differentiation antigens thus provides evidence of other maturation-linked characterizations that can be evaluated to assess the differentiative state of ANLL cells.

Evaluation of the morphologic appearance of cells also did not strictly correlate with the antigenic phenotype. An immature appearance (FAB-M1 cell) was not necessarily associated with expression of an antigen predominantly found on immature granulocytes (L4F3) nor was a more mature appearance (FAB M3) associated with expression of an antigen found on mature granulocytes (T5A7). There were, however, two FAB subclasses that demonstrated distinct patterns of antigenic expression. Specifically, most of the specimens of FAB M1 ANLL did not express the antigen detected by 1G10 (12 of 15). This antigen is expressed by virtually all granulocytic cells except the least mature myeloblasts and CFU-GM (where only a portion are 1G10 positive). In the second instance FAB M4 specimens frequently reacted with all of the antibodies used in the present study, consistent with the multiple expression of cytoplasmic enzymes detected by histochemic methods. Nevertheless, analysis of cell surface antigens provides an independent assessment and can provide a novel basis for the classification of patients with ANLL.

A number of other investigators have examined the expression of myeloid antigens on ANLL cells.[15-22] Herrmann et al[17] demonstrated quantitative differences in the number of ANLL cells expressing antigens in the various subgroups defined by the FAB classification. One of the monoclonal antibodies used was VIMD5, which also reacts with the X-hapten.[23] Analogous to our results with 1G10, they found the X hapten on only 15% to 30% of the FAB M1 leukemias tested, which was a lower proportion than that found for the other FAB subclasses, except for M6.

Griffin et al[20] defined patterns of antigen expression with a series of monoclonal antibodies that correspond to discrete levels of differentiation. They observed patterns that corresponded to some FAB groups, that is, M3 and M5, but these patterns were not exclusively expressed by leukemias of these subtypes, and the number of patients in these groups was small. Similar to our results with 5F1, MY-4, an antibody that reacts with monocytes, was expressed by some samples that were NSE negative. This is in contrast to a study in which monoclonal antibodies were described that reacted with nearly every case of FAB M4 and M5 leukemia tested.[21]

Of potential interest is that antigenic phenotyping of ANLL with these antibodies may identify groups of prognostic importance. The FAB classification has been only minimally successful in identifying groups of clinical relevance. In a preliminary report by Vaughan et al[24] a correlation between successful remission induction and reactivity with MY-1, another antibody to the X-hapten, was reported.[25] In contrast, Griffin et al[20] failed to detect a relationship between antigenic phenotype and probability of remission induction. Unfortunately, the patients in the present study with ANLL were collected over a 10-year period and were not treated in a uniform fashion and therefore a clinical analysis is not possible. We are, however, presently using these antibodies to study a larger number of pediatric patients in a prospective manner who are enrolled in clinical protocols of the Children's Cancer Study Group.

A subclassification of ANLL that is not accounted for in the FAB schema is acute megakaryoblastic leukemia. One patient who was not included in the present series experienced a classical course of acute megakaryblastic leukemia.[26] Leukemic cells from this patient failed to react with any of the antibodies used in the present study although they did react with C7E10, an antibody prepared in our laboratory to glycoprotein Ib.[27] Nineteen specimens of ANLL included in the present study were found not to react with C7E10 (data not shown).

In the present study we also examined leukemic cells of lymphoid origin and observed that antibodies 1G10, 5F1, and L4F3 are potentially useful in differentiating ALL from ANLL. Ninety-five percent of the cases of ANLL tested reacted with at least one of these three antibodies. Eighty-three percent of the ANLL samples tested reacted with either 1G10 or 5F1 or both. None of the 63 cases of ALL tested reacted with either of these antibodies. Thus, these antibodies are potentially useful in cases where the differentiation between these diseases is not straightforward. In a previous report, we identified two such patients who were diagnosed as having ALL although their leukemic cells reacted with 1G10 and/or 5F1. These patients were subsequently reclassified as ANLL, based on a change in morphology in one patient and in the clinical course in the other. Cells from these two patients failed to express CALLA, B-cell, or T-cell antigens.[12]

Reactions of antimyeloid antibodies with cells that were unequivocally of lymphoid origin were also observed in a number of instances. Antibody L4F3, which reacted with 90% of the ANLL specimens tested also reacted with 8% of the ALL samples tested. Similarly, Griffin et al have reported that MY-9 reacted with 90% of ANLL specimens, and with 2% of ALL specimens obtained from adults.[9] Studies in this laboratory have shown that L4F3 and MY-9 may detect the same antigen as determined by competitive binding-inhibition studies (unpublished observation, R. Andrews). Furthermore, antibody T5A7 reacted with 32% of the ALL samples tested, especially with T cell leukemias. This reactivity with T-cell leukemias is not surprising since T5A7 is known to react with PHA-stimulated lymphocytes. The evaluation of additional patients with ALL who express these antigens is required to assess the clinical significance of these unexpected expressions of myeloid-associated antigens on leukemic cells of lymphoid origin.

Monoclonal Antibodies Binding to the Human Neutrophil C3bi Receptor Have Disparate Functional Effects

Dennis D. Hickstein, Richard M. Locksley, Patrick G. Beatty, Anajane Smith, Diane M. Stone, and Richard K. Root

Three monoclonal antibodies (MAb)—OKMI, 7C3, and 60.3—immunoprecipitated a common 170-kd neutrophil membrane antigen closely associated with, or identical to, the C3bi receptor (CR3). Despite binding to a common receptor, these antibodies displayed marked differences in their effects on C3bi-mediated neutrophil function as assessed by the binding and ingestion of opsonized zymosan and the subsequent triggering of the respiratory burst. Antibody 7C3 caused a time-dependent, irreversible inhibition of the neutrophil oxidative response to opsonized zymosan that correlated with capping of the bound antibody. In contrast, antibody 60.3 caused an immediate inhibition of the neutrophil oxidative response to opsonized zymosan that required the continuous presence of exogenous antibody to achieve the maximal inhibitory effect. Antibody OKMI demonstrated minimal inhibition of O_2^- release. Despite their functional differences, binding of either 7C3 or 60.3 led to up-regulation of new antigen, presumably from intracellular sites as previously described using OKMI. Crossed immunoprecipitations of radiolabeled neutrophil lysates indicated that each MAb bound to different antigens near or within the CR3 complex. Thus three MAb binding to the neutrophil CR3 receptor each caused receptor up-regulation but had markedly different functional effects on the cell.

© 1986 by Grune & Stratton, Inc.

RECEPTORS for the complement fragment C3bi (CR3) located on the surface membrane of human neutrophils mediate the binding and ingestion of particles coated with this opsonin, and therefore are critically involved in cellular host defense.[1,2] The development of monoclonal antibodies (MAb) directed against this receptor has provided the opportunity to investigate the consequences of alterations in receptor number and activity. We compared two recently described MAb, 7C3[3,4] and 60.3,[5,6] previously reported to inhibit C3bi-mediated neutrophil function, to investigate the cellular response to antibody-mediated receptor blockade. The effects of these MAb were compared with those induced by OKM1, a third MAb known to bind to the neutrophil C3bi receptor.[7] The relationships among these antibodies were further elucidated by the biochemical characterization of the antigens immunoprecipitated by these antibodies.

MATERIALS AND METHODS

Monoclonal antibody production, purification, and creation of F(ab')$_2$ fragments Antibody 60.3 (IgG$_{2a}$) was produced as previously described [5] Antibody for experimental use was collected as ascites fluid from pristane-primed mice that had been inoculated with approximately 10^6 hybridoma cells. After purification using affinity chromatography with protein A-Sepharose (Pharmacia Fine Chemicals, Uppsala, Sweden),[8] 60.3 was aliquoted and stored at −70 °C before experimental use. For designated experiments the antibody was directly fluoresceinated with fluorescein isothiocyanate (FITC; Research Organics, Cleveland),[9] or radioiodinated with ^{125}I (New England Nuclear, Boston) using the iodogen method.[10] Antibody concentration was determined using the Bradford assay.[11]

Antibodies 7C3 (IgG$_3$) and 31D8 (IgG$_1$), kindly provided by Dr Harry Malech, Yale University, New Haven, Conn, were produced as described.[3] Antibody 7C3 was recloned to the single-cell level by limiting dilution before use. Antibody was collected from murine ascites fluid, purified using protein A-Sepharose,[8] and stored at −70 °C Antibodies 7C3 and 31D8 were linked to FITC or ^{125}I as described for antibody 60.3. Antibody OKM1 (IgG$_{2b}$)[7] was obtained from Ortho Diagnostic Systems, Raritan, NJ, purified using Sephacryl S-200, and conjugated with FITC or ^{125}I as described for the other antibodies. MAb 31D8 binds to neutrophils at a site distinct from the C3bi receptor (D.H., unpublished observation, November 1984); this MAb served as a control antibody in designated experiments.

F(ab')$_2$ fragments of MAb 7C3 and 60.3 were produced after incubation with immobilized pepsin (Pierce Chemical Co, Rockford, Ill) for two hours at 37 °C at pH 4 5 [12] Protein A-Sepharose was used to absorb F$_c$ fragments and residual intact immunoglobulins. The purity of the eluted F(ab')$_2$ fragments was established after sodium dodecyl sulfate (SDS)-polyacrylamide gel electrophoresis (PAGE) under nonreducing conditions.

Neutrophil preparation. Peripheral blood was obtained from normal volunteers in accordance with institutional protocols, or as leukopaks obtained from normal donors during plateletpheresis at Puget Sound Blood Center, Seattle Neutrophils were isolated by dextran sedimentation at 37 °C either directly or after density-gradient centrifugation through Ficoll-Hypaque (Histopaque; Sigma Chemical Co, St Louis).[13] Residual erythrocytes were removed by hypotonic lysis. Cells were washed and resuspended in Hanks' balanced salt solution (HBSS) at the desired concentration as determined by the neutrophil number, viability, and differential count. The purified neutrophil fraction contained 85% to 98% polymorphonuclear cells (PMNs) when isolated after Ficoll-Hypaque and 65% to 85% PMNs without this initial step. Viability was always greater than 97% as assessed by trypan blue exclusion.

Binding of monoclonal antibodies to PMNs. Saturating concentrations of each antibody were determined by incubating 5 × 10^5 neutrophils with increasing dilutions of MAb at 4 °C for 30 minutes in round-bottom microtiter wells (Linbro, Flow Laboratories, McLean, Va) in a final volume of 100 μL HBSS. Cells were washed twice with HBSS at 4 °C to remove unbound antibody and incubated at 4 °C for 30 minutes with 25 μL of a 1:50 dilution of affinity-purified, fluorescein-conjugated, sheep antimouse F(ab')$_2$ antiserum

(Cappel, Cochranville, Pa). After two further washes, cells were fixed with 1% paraformaldehyde in normal saline at 4 °C for 15 minutes.

Immunofluorescence of these neutrophils was quantitated using an Ortho 50 H cytofluorograph interfaced to a model 2150 Computer (Ortho Diagnostic Instruments, Westwood, Mass). Fluorescent excitation used a wavelength of 488 nm; emission was measured at 515 to 575 nm. The fluorescent signal was log amplified by selection of the photomultiplier setting. Neutrophils were gated selectively from lymphocytes and monocytes on the basis of right- and forward-angle light scatter. The mean fluorescent intensity for the neutrophil population at each antibody dilution was measured and plotted on logarithmic paper. The point of departure from the plateau of the curve was determined to be the minimum saturating concentration. The dilution of each antibody used experimentally was at least twofold higher than the minimal saturating dose. Using these criteria, the following amounts of antibody were required per 5×10^5 cells: antibody 3ID8, 0.75 µg; antibody 60.3, 2 µg; antibody 7C3, 0.75 µg; antibody OKMI, 0.4 µg.

In the assessment of temperature and time of incubation on PMN-associated fluorescence, PMNs were incubated with saturating concentrations of FITC-linked antibodies at 4 °C for 30 minutes, washed free of unbound antibody, and incubated at 4 °C or 37 °C for five or 30 minutes before fixation. Mean fluorescence of the PMN population was quantitated by flow cytometry. The percentage of maximal fluoresence of the cell population was obtained by converting the log fluorescent values to linear values, subtracting the control cell values, and expressing the result as a percentage of the maximal linear fluorescence. In direct immunofluorescence experiments, the maximal fluorescence was that obtained by neutrophils exposed to a fluorescent first antibody and not subjected to further experimental manipulation

In the indirect immunofluorescence assay, PMNs were incubated with saturating concentrations of antibody at 4 °C for 30 minutes, washed free of unbound antibody, and incubated at 4 °C or 37 °C for five or 30 minutes before fixation and incubation with the FITC-labeled second antibody. After washing, the mean fluorescence of the cell population was quantitated by flow cytometry. The percentage of maximal fluorescence was calculated as described for the direct immunofluorescence assay, except that the maximal fluorescence referred to that of neutrophils exposed to the MAb and not subjected to further experimental manipulation before incubation with the FITC-labeled second antibody.

In co-capping studies, 5×10^6 PMNs were incubated simultaneously in microtiter wells at 4 °C or 37 °C for 30 minutes with saturating concentrations of MAb 7C3 and FITC-60.3 or FITC-OKM1 After fixation and washing to remove unbound antibody, cells were examined using fluorescent microscopy. These studies were repeated using $F(ab')_2$ fragments of MAb 7C3 and FITC-60.3 or FITC-OKM1.

The effect of MAb 7C3 on the binding of the other two antibodies was assessed in two separate experiments. PMNs (5×10^5) were incubated with saturating concentrations of MAb 7C3 or $F(ab')_2$ fragments of 7C3 at 4 °C for 30 minutes and then incubated at 4 °C or 37 °C for 30 minutes before fixation and incubation with FITC-60.3 or FITC-OKM1. PMNs were washed to remove unbound antibody and examined using both fluorescent microscopy and flow cytometry.

For direct studies using iodinated antibodies, ^{125}I-labeled antibody (50,000 cpm) was incubated with 5×10^5 cells at 4 °C for 30 minutes in a total volume of 100 µL in 96-well microtiter plates (Costar, Cambridge, Mass). Cells were washed and incubated at 4 °C or 37 °C for zero or 30 minutes before centrifugation through 300 µL of a suspension of dinonyl phthalate (one part) and dibutyl phthalate (four parts) silicon oil. After removal of the supernatant silicon oil, the cell-bound radioactivity remaining in the pellet was determined. Nonspecific ^{125}I-antibody binding was determined by saturating the cells with a 100-fold excess of unlabeled MAb before exposure to the ^{125}I-labeled antibody. Specific antibody binding was calculated by subtracting values for nonspecific binding from those obtained with cells incubated with ^{125}I-labeled antibody alone.

The indirect ^{125}I assay was performed by incubating 5×10^5 cells with saturating concentrations of MAb at 4 °C for 30 minutes, washing, and subsequently resuspending and incubating the cells at 4 °C or 37 °C for zero or 30 minutes. Cells were then fixed with paraformaldehyde and incubated with ^{125}I-labeled sheep antimouse $F(ab')_2$ (50,000 cpm). After 30 minutes, cells were centrifuged through silicon oil as described, and the residual radioactivity in the pellet was counted. Values for nonspecific ^{125}I-antibody binding were obtained by incubating cells with the second antibody alone. These values were subtracted from those measured for MAb-coated cells to determine specific binding.

Quantitation of antigen binding sites was performed using ^{125}I-labeled $F(ab')_2$ fragments of MAb 60.3 and 7C3. Human PMNs (2×10^6 cells) were incubated with increasing concentrations of labeled antibody in the absence or presence of 100-fold molar excess of unlabeled antibody. After incubation for 60 minutes at 4 °C, PMNs were separated from unbound antibody by centrifugation through 300 µL of phthalate oil as described in the direct iodination studies. Radioactivity remaining in the pellet was used to calculate specific binding, the amount of antibody bound, and the bound/free ratio was determined. The number of antibody binding sites per PMN was estimated using Scatchard analysis [14]

Conditions of MAb binding for functional studies. Two conditions for MAb binding were examined in parallel. Under "antibody present" conditions, 5×10^5 PMNs were incubated with antibody at 37 °C for ten minutes and membrane stimulants were then added directly to the reaction mixture. In the "antibody removed" conditions, PMNs were incubated with antibody (4 °C for 30 minutes), washed at 4 °C to remove unbound antibody, and warmed to 37 °C over ten minutes before membrane stimulation. Thus exogenous antibody was present at the time of stimulation under "antibody present" conditions but was removed before stimulation under "antibody removed" conditions. Control conditions examined concurrently included identically handled PMNs that had not been exposed to antibody or that had been incubated with control monoclonal antibody 31D8.

Stimuli. Zymosan particles (Sigma) were preopsonized with pooled human serum that had been stored undiluted at −70 °C after collection. Opsonized particles were prepared daily after incubation at 37 °C for 30 minutes in 50% human serum in HBSS. Zymosan was washed and resuspended in HBSS before use A single batch of zymosan was used for all experiments. Controls were performed with the same zymosan preparation each day. Zymosan particles prepared in this manner did not bind FITC-labeled MAb 60.3, 7C3, OKM1, or 31D8. Phorbol myristate acetate (PMA; Consolidated Midland Corp, Brewster, NY) was dissolved in dimethyl sulfoxide at 1 mg/mL and stored at −70 °C until use. FITC was coupled to immunological grade zymosan (ICN Nutritional Biochemicals, Cleveland) as described.[15] The FITC-zymosan was aliquoted and stored at −20 °C before opsonization on the day of use with pooled human serum as described

Superoxide release. Superoxide (O_2^-) release was measured directly in Linbro flat-bottomed, 96-well microtiter plates (Flow Laboratories) using a modification of the Pick and Mizell[16] microassay for superoxide dismutase (SOD; Sigma)-inhibitable ferricytochrome c (Sigma) reduction. The microtiter wells were first incubated with 100 µL gelatin (0.5 mg/mL) to decrease the O_2^- release by unstimulated neutrophils and washed with HBSS before use. The reaction mixture contained 5×10^5 neutrophils prepared under the conditions described above, 10.9 nmol ferricytochrome c and 20 μL MAb with or without 20 μg SOD in a final volume of 100 μL HBSS. MAb were used in concentrations previously demonstrated to saturate binding sites on PMNs. Either PMA (100 ng/mL) or serum opsonized zymosan (particles: cells = 10:1) were added in 10-μL vol. After incubation at 37 °C for 20 minutes on a microshaker (setting 3; Dynatech Laboratories, Alexandria, Va), the change in the light absorption at OD 550 was measured using a Titertek Multiscan (Titertek; Flow Laboratories). Total reducable ferricytochrome c was determined after adding 10 μL of a saturated sodium dithionate solution to each well and remeasuring the OD 550. For each time point the SOD-inhibitable ferricytochrome c reduced was calculated as a percentage of the total dithionite-reducable ferricytochrome c and multiplied by 10.9 nmol to calculate the total nmol of O_2^- released. Due to variation in the calculated extinction coefficient for reduced ferricytochrome c at different concentrations of the compound, this method was demonstrated to be most reproducible. In preliminary experiments, none of the MAb interfered directly with ferricytochrome c reduction. Interference with transmission of the light signal by zymosan in the O_2^- assay was corrected by subtraction of the SOD-containing wells used as a blank.

H_2O_2 release. Release of H_2O_2 was measured by the oxidation of scopoletin as previously described.[17]

Determinations of cell-associated particles. After preparation with MAb under the "antibody present" or "antibody removed" conditions as described, 5 × 10^5 PMNs were incubated in gelatin-blocked Linbro microtiter plates at 37 °C with continuous agitation with opsonized FITC-zymosan (particles: cells = 10:1) in 100 μL HBSS. After 20 minutes, cells were fixed with 1% paraformaldehyde, washed twice, and transferred to glass slides for examination by fluorescence microscopy. The number of zymosan particles within the borders of 100 consecutive PMNs was recorded.

Samples prepared in parallel were assessed for cell-associated fluorescence by flow cytometry The threshold fluorescence intensity used was that at which 99% of the total cell population not exposed to FITC-zymosan was negative. With flow cytometry, control neutrophils demonstrated a mean fluorescence of less than or equal to 20; PMNs with a fluorescence greater than or equal to 80 on a log scale contained cell-associated, FITC-linked zymosan. This fluorescence intensity represented a tenfold increase in brightness when at least one FITC-zymosan was associated with a neutrophil. Prolonged incubation (longer than 30 minutes) of PMNs with FITC-zymosan was associated with a mild decrement in cell-associated fluorescence. This did not adversely affect the assay, since the intensity of fluorescence of the labeled zymosan permitted reliable detection despite mild attenuation of the signal.

Immunoprecipitation and gel electrophoresis. PMNs (5 × 10^7 cells) were surface labeled with ^{125}I using a modification of the lactoperoxidase procedure.[18] After cell lysis by incubation in 0.5% NP40, 0.15 mol/L NaCl, 0.05 mol/L Trizma, and 2 mmol/L phenylmethylsulfonyl fluoride (PMSF; Sigma), immunoprecipitations were performed using 50 μg purified MAb coupled to cyanogen bromide-activated Sepharose 4B (Pharmacia). In the crossed immunoprecipitation experiments, the cell lysates were extensively precleared with the "preclearing antibody" before the addition of the precipitating antibody. One-dimensional SDS-PAGE was performed under reducing conditions according to the method of Laemmli.[19]

Statistical analysis. The paired *t* test was used to assess the statistical significance of the results shown in the designated figures and tables.

RESULTS

Inhibition of C3bi-mediated PMN respiratory burst activity by MAb. The comparative ability of these antibodies to inhibit O_2^- release was measured to relate these studies to previously reported findings (Table 1).[3] Monoclonal antibody 31D8, not known to affect C3bi function, was used as an antibody control. Although all three antibodies, 7C3, 60.3, and OKM1, demonstrated an effect on PMN respiratory burst activity triggered by opsonized zymosan, the extent of inhibition and the conditions required for the maximal inhibitory effect were markedly different. Antibody 7C3 exerted its major effect when exogenous antibody was removed after 30 minutes' preincubation with PMNs. When exogenous 7C3 antibody was present during the assay, O_2^- release was inhibited only slightly compared with control antibody-treated PMNs. In contrast, antibody 60.3 markedly suppressed zymosan-triggered O_2^- release when antibody was present. When 60.3 was removed after preincubation with cells, O_2^- release increased to levels approaching control values. Antibody OKM1 had a modest inhibitory effect on zymosan-generated O_2^- release that was only observed in the presence of exogenous antibody. Similar results were obtained when H_2O_2 release, rather than O_2^-, was measured (data not shown). None of these antibodies significantly affected O_2^- release in response to PMA over 20 minutes. None of the antibodies were cytotoxic under the conditions used as assessed by trypan blue exclusion.

When these experiments were repeated using $F(ab')_2$ fragments, antibody 60.3 inhibited O_2^- release to levels almost identical to those observed with the intact MAb, ie, O_2^- release was inhibited to 38.5% of control when the $F(ab')_2$ fragment was present (n = 3) and to 78.3% of control when the $F(ab')_2$ fragment was removed after preincubation (n = 3). Inhibition of O_2^- release by the $F(ab')_2$ fragment of MAb 7C3 followed the pattern demonstrated for the intact antibody. The antibody fragment inhibited O_2^- release to 76% of control when antibody was present (n = 4) and to 64% of control when antibody was removed after preincubation (n = 6).

Table 1. Effect of MAb on Superoxide Release by Human PMNs

Control (27)	PMA 7.3 ± 0.2	Opsonized Zymosan 2.0 ± 0.18
Antibody Present	% Control	
3ID8 (5)	93.9 ± 2.4	93.7 ± 5.8
7C3 (4)	98.0 ± 2.7	86.4 ± 5.6
60.3 (13)	99.2 ± 3.4	34.7 ± 5.4*
OKMI (9)	98.5 ± 3.9	81.0 ± 8.0†
Antibody Removed		
3ID8 (5)	94.9 ± 2.1	97.6 ± 5.0
7C3 (4)	106.0 ± 2.1	62.8 ± 2.6†
60.3 (13)	97.3 ± 2.0	79.1 ± 6.3
OKMI (9)	95.6 ± 1.8	104.0 ± 7.7

Superoxide release was measured over 20 minutes by SOD-inhibitable ferricytochrome c reduction as described in Materials and Methods. Values shown are the mean ± SEM for the number of experiments shown in parentheses. Values for controls represent nmol $O_2^-/5 \times 10^5$ PMN/20 min with the number of experiments shown in parentheses. Unstimulated control neutrophils released 0.72 ± 0.13 nmol $O_2^-/5 \times 10^5$ PMN/20 min

*$P < .005$ when compared with antibody 3ID8.

†$P < .025$ when compared with antibody 3ID8.

Kinetics of antibody-mediated interference with PMN respiratory burst activity. The incubation times required for antibodies 7C3 and 60.3 to exert their inhibitory effects on zymosan-triggered O_2^- release were investigated (Fig 1). PMNs were incubated with saturating concentrations of antibody at 37 °C for 0, 10, 20, or 30 minutes before opsonized zymosan was added to the reaction mixture. Superoxide generation was assayed 20 minutes after the addition of zymosan. The decrease in O_2^- release by PMNs incubated with 7C3 was linearly related to the time of exposure of neutrophils to 7C3 before stimulation. In contrast, incubation of antibody 60.3 with neutrophils produced an immediate, profound inhibition of O_2^- release that did not change by prolonging the duration of antibody exposure to neutrophils before stimulation. Temperature during preincubation did not appear to be a critical factor, since PMNs incubated with 7C3 at 4 °C before the addition of zymosan had comparably reduced O_2^- release.

Cell-associated particles. Neutrophils were prepared with the designated antibodies as described and then incubated with opsonized, FITC-linked zymosan (Table 2). The number of cell-associated particles was determined by both direct microscopic and flow cytometric assays. As with the O_2^- assay, the maximal inhibitory effect of 7C3 required a 30-minute preincubation of cells with antibody. In contrast, 60.3 exhibited an immediate inhibitory effect that required the presence of antibody in the reaction media for maximal inhibition. Antibody OKM1 displayed a slight inhibitory effect under "antibody present" conditions.

Kinetics of antibody binding. To determine whether the differences in time of onset of action of 7C3, as compared with 60.3 and OKM1, were related to differences in antibody binding rates, the kinetics of antibody binding were assessed by flow cytometry. Using directly fluoresceinated 7C3, 60.3, or OKM1, each antibody achieved complete saturation of binding to neutrophils within 15 minutes at both 4 °C and 37 °C (data not shown). Incubation of cells with saturating concentrations of 60.3 or OKM1 did not inhibit the binding of 7C3 or of each other, as assessed by flow cytometry.

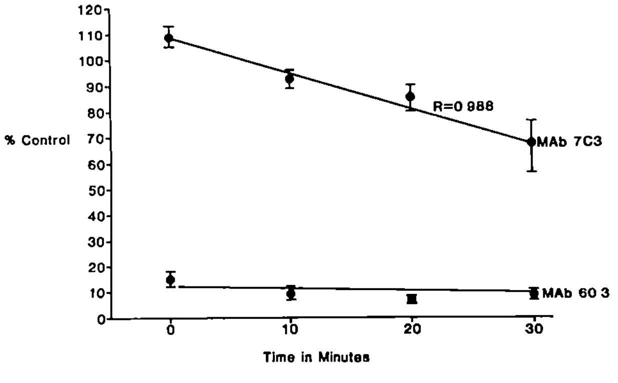

Fig 1. Effect of time of exposure of neutrophils to MAb on subsequent ability to trigger O_2^- release by opsonized zymosan. Time of exposure (shown on the abscissa) refers to the duration of incubation of MAb with neutrophils before the addition of opsonized zymosan. All assays were read 20 minutes after the addition of the stimulus. Control PMNs released 2.2 ± 0.3 nmol of O_2^- per 5×10^6 PMNs per 20 minutes. For 7C3, the r value equaled 0.988.

Table 2. Influence of MAb on Cell Association of FITC-Linked Opsonized Zymosan With PMN

	Cell-Associated Particles (%)	
	Microscopic	Flow Cytometry
Antibody Present		
Buffer (6)	62.3 ± 12.5	45 ± 4.6
Antibody 31D8 (6)	67.0 ± 7.8	50 ± 4.1
Antibody 60.3 (6)	34.2 ± 11.0*	16 ± 2.4†
Antibody 7C3 (6)	52.3 ± 13.7	42 ± 3.8
Antibody OKMI (3)	50.0 ± 1.1	ND
Antibody Removed		
Buffer (6)	53.7 ± 9 3	50 ± 1.4
Antibody 31D8 (6)	53.3 ± 8.9	52 ± 1.2
Antibody 60 3 (6)	57.7 ± 11.1	45 ± 1 4
Antibody 7C3 (6)	37.5 ± 17.6*	37 ± 1.2*
Antibody OKMI (3)	59.3 ± 4.5	ND

Microscopic percentage of cell association was obtained by counting 100 consecutive PMNs and determining the percentage of cells containing one or more zymosan particles. Flow cytometry percentage of cell association was determined by assessing the percentage of PMNs with a fluorescent intensity indicating that one or more zymosan particles was PMN associated. Data represent the means ± SD for the number of experiments shown in parentheses. ND, not done.

†$P < .01$.

Detection of cell-associated antibody. Directly fluoresceinated 60.3 was used to determine whether the recovery of function by 60.3 pretreated cells after washing could be related to a loss of cell-associated 60.3. Comparative studies were carried out with FITC-7C3, FITC-OKM1, and FITC-31D8. Neutrophils were preincubated with saturating concentrations of FITC-MAb at 4 °C for 30 minutes, washed free of unbound antibody, and then incubated at 4 °C or 37 °C for five or 30 minutes before fixation and quantitation of fluorescence by flow cytometry.

The mean fluorescence of neutrophils incubated at 4 °C after exposure to each FITC-antibody did not differ significantly from that of cells fixed immediately after incubation with antibody (Table 3). Incubation of FITC-7C3–treated neutrophils at 37 °C resulted in a prompt drop in the fluorescence intensity by five minutes, which remained constant at 30 minutes. After warming to 37 °C, the fluorescence of FITC-60.3– or FITC-OKM1–treated neutrophils decreased slowly to 80% of maximal by 30 minutes. Neutrophils exposed to FITC-31D8 and warmed to 37 °C demonstrated no loss of cell-associated fluorescence.

Detection of PMN surface-associated antibody. Indirect immunofluorescence was investigated to determine whether the antibody remained associated with the cell surface after antibody binding and warming (Table 4). After PMNs were incubated at 4 °C with saturating concentrations of antibody, cells were washed and maintained at either 4 °C or 37 °C for five or 30 minutes before fixation and indirect immunofluorescence. The results paralleled those observed with direct immunofluorescence. There was no significant decrement in the mean fluorescence of any of the cell populations when incubations were carried out at 4 °C

Table 3. Effect of Temperature and Time of Incubation on PMN-Associated Fluorescence After Binding of FITC-Linked MAb

	Monoclonal Antibody (%)			
Incubation Time	31D8	60.3	7C3	OKMI
4 °C for 0 min	100	100	100	100
4 °C for 5 min	99.0 ± 2.1	92.0 ± 1.7	97.1 ± 1.5	90.3 ± 4.3
4 °C for 30 min	95.0 ± 3.9	93.5 ± 2.6	97.0 ± 1.2	97.6 ± 1.1
37 °C for 5 min	122.0 ± 4.6	95.5 ± 1.4	56.2 ± 4.0*	104.7 ± 6.8
37 °C for 30 min	111.0 ± 2.6	80.5 ± 6.1	54.6 ± 7.3†	83.9 ± 6.1

Results are expressed as the percentage of maximal fluorescence, where 100% equaled the fluorescence of PMNs preincubated with FITC-antibody and fixed at zero minutes (immediately after washing away unbound antibody). Values shown are mean ± SEM for three experiments.

*$P < .01$ when compared with results at 4 °C.

†$P < .05$ when compared with results at 4 °C.

for five or 30 minutes. However, at 37 °C the fluorescence saturation of 7C3-treated cells dropped to less than 50% by 30 minutes. In contrast, 60.3 and OKM1 demonstrated only a modest decrement in surface antibody after incubation at 37 °C for 30 minutes. These studies of cell- and surface-associated antibody were confirmed in studies using iodinated MAb (data not shown).

Morphological changes in PMNs incubated with 7C3 or 60.3. After incubation with FITC-7C3 or FITC-60.3, PMNs were warmed on a glass microscope slide and examined by fluorescence microscopy. When cells were maintained at 4 °C, both antibodies displayed a uniform, rim appearance on the cell. With warming for 30 minutes, however, more than 90% of cells incubated with 7C3 displayed significant capping of the antigen (Fig 2). In contrast, less than 10% of cells treated with 60.3 displayed capping after 30 minutes. Results similar to those observed for antibody 60.3 were seen using FITC-OKM1 (data not shown).

When PMNs were directly incubated with MAb 7C3 and FITC-OKM1 or FITC-60.3 at 4 °C or 37 °C, the fluorescence did not redistribute into the polar cap. Instead, the fluorescence remained circumferentially distributed at both temperatures. This pattern appeared with both intact MAb 7C3 and the $F(ab')_2$ fragment of 7C3.

Up-regulation of antigens. Whereas the time-related effect of 7C3 on PMN dysfunction correlated with antibody-induced membrane capping, the mechanism by which neutrophils recovered function after removal of exogenous 60.3 remained unclear. For these experiments PMN were incubated at 4 °C with saturating concentrations of 60.3 that blocked the subsequent binding of FITC-60.3 to cells maintained at 4 °C. Warming these cells to 37 °C resulted in the rapid reappearance of 60.3 surface antigen, as detected by the binding of newly added FITC-60.3 to the surface of the warmed cells (Fig 3). If PMNs were stimulated with either PMA or opsonized zymosan (100:1 particle to cell ratio) after exposure to the blocking antibody but before exposure to FITC-60.3, the amount of surface antigen increased to one and one half times that seen in PMNs not exposed to the stimuli. Comparable results were obtained using ^{125}I-60.3 antibody (data not shown).

Because up-regulation of the 60.3 antigen seemed to correlate with the recovery of PMN responsiveness to C3bi-coated particles, experiments were performed using antibodies 7C3 and OKM1. Surprisingly, each of these antigens was up-regulated in a similar fashion (Fig 3). Although most of the binding of FITC-60.3, FITC-OKM1, and FITC-7C3 was due to the appearance of "new" antigenic sites, some of this binding reflected the appearance of "old" sites from which the cold antibody had dissociated It was more difficult to blockade 7C3 binding sites completely, presumably reflecting the relative ease with which antibody 7C3 was shed (Table 3 and Table 4). When the control antibody 31D8 was used, an increase in antigen binding sites was not observed relative to cells warmed to 37 °C without additional stimulation.

Because of the morphological changes induced by 7C3, we examined the capacity of the PMNs to up-regulate the 60.3 and OKM1 binding sites after incubation with 7C3. In two separate experiments, PMNs saturated with MAb 7C3 at 4 °C and warmed to 37 °C up-regulated FITC-60.3 and

Table 4. Effect of Temperature and Time of Incubation on PMN Surface-Associated Antibody After Binding Using Indirect Immunofluorescence

	Monoclonal Antibody (%)			
Incubation Time	31D8	60.3	7C3	OKMI
4 °C for 0 min	100	100	100	100

Results are expressed as the percentage of maximal fluorescence, where 100% equaled the fluorescence of PMNs preincubated with antibody, fixed at zero minutes (immediately after washing away unbound antibody), and immediately incubated with the fluorescent second antibody. Values shown are mean ± SEM for three experiments.

*$P < .01$ when compared with results at 4 °C

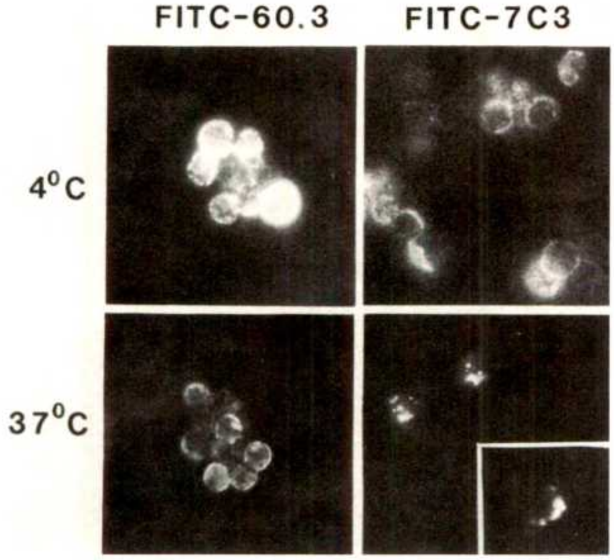

Fig 2. Fluorescence microscopy of FITC-7C3- and FITC-60.3-treated neutrophils. Neutrophils were maintained at 4 °C (upper panels) or 37 °C (lower panels) after incubation with the FITC-linked antibodies (Planapo, ×50). Insert (lower right) demonstrates capping of 7C3 observed under higher magnification (Planapo, ×63).

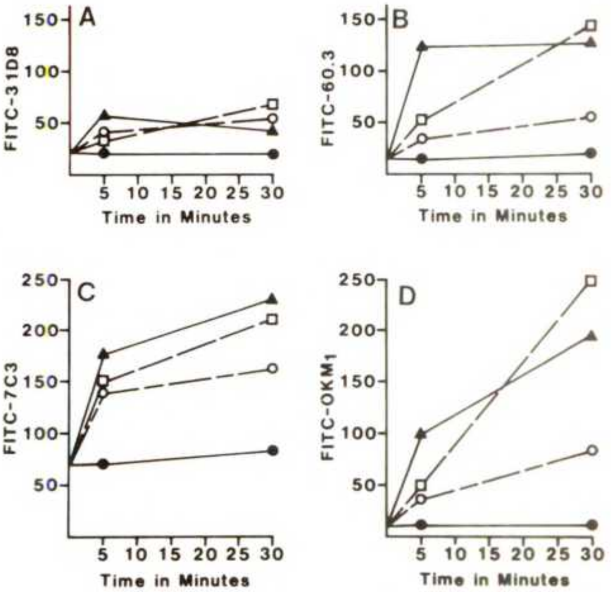

Fig 3. Appearance of new antigen sites on antibody-pretreated PMNs incubated under resting conditions at 4 °C (●—●) or 37 °C (○—○) and stimulated conditions at 37 °C with PMA (▲) or opsonized zymosan (□). Percentage of maximal fluorescence (see Materials and Methods) is shown on the ordinates. Cells were saturated with nonfluorescent antibody at 4 °C and washed free of unbound antibody before incubation and subsequent exposure to FITC-antibody. Data shown are the mean of three experiments.

FITC-OKM1 binding sites by 50% (as assessed by flow cytometry) compared with cells warmed to 37 °C without prior exposure to 7C3. $F(ab')_2$ fragments of 7C3 had an identical effect on PMNs.

Quantitation of antigen binding sites. To determine whether the differential effect of these MAb on PMN function was related to different antigenic density on the cell surface, the number of antigen binding sites for MAb 60.3 and 7C3 was estimated using Scatchard analysis. $F(ab')_2$ fragments of MAb 60.3 detected approximately 123,000 sites per PMN, whereas $F(ab')_2$ fragments of MAb 7C3 detected 156,000 sites per PMN.

Immunoprecipitation. Antigens were immunoprecipitated from cell lysates of ^{125}I-labeled human PMNs using sepharose-linked antibodies (Fig 4). Under reducing conditions using SDS-PAGE, antibody 60.3 identified four bands with approximate molecular weights (mol wt) of 180 kd, 170 kd, 150 kd, and 110 kd. Antibody 7C3 immunoprecipitated three antigens, two of which migrated identically (170 kd, 110 kd) to those identified by antibody 60.3. The third band precipitated by 7C3 migrated with an approximate mol wt of 130 kd. OKM1 detected two bands (approximate mol wt 170 kd and 110 kd) that appeared identical to two of the antigens detected by 60.3 and 7C3.

Although preclearance of the cell lysate with antibody 7C3 neither removed the four bands detected by 60.3 nor the two bands detected by OKM1 (Fig 5), in several experiments the amount of α-chain precipitated by 60.3 and OKM1 was slightly reduced by preclearance with 7C3. Preclearance by 60.3 completely removed the OKM1 antigen and all but the 130-kd band detected by 7C3. Preclearance of the lysate with antibody 7C3 removed all 7C3 antigen, and preclearance with antibody 60.3 removed all of the 60.3 antigen. Preclearance with OKM1 antibody removed the 170-kd and diminished the 110-kd antigens identified by 60.3 but only minimally reduced the 170-kd and 110-kd bands and did not affect the 130-kd band precipitated by 7C3 (data not shown).

DISCUSSION

These studies demonstrate that three MAb, each of which interacts with antigens closely associated with the neutrophil C3bi receptor, have markedly different functional effects on

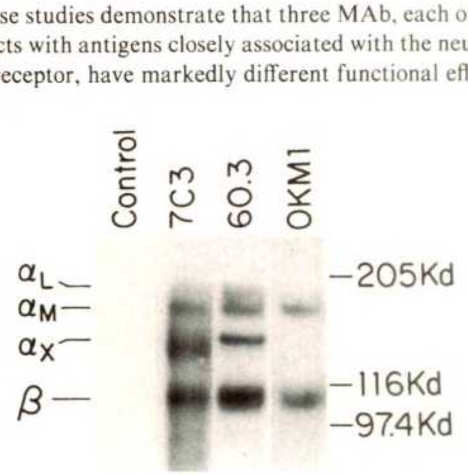

Fig 4. Polyacrylamide gel (7%) electrophoresis of ^{125}I-labeled immunoprecipitates of antibodies 7C3, 60.3, and OKMI from human neutrophils. The immunoprecipitates from the control anti-neutrophil MAb (lane 1), antibody 7C3 (lane 2), antibody 60.3 (lane 3), and antibody OKMI (lane 4) are shown. The α_L, α_M, α_X, and β-subunit designation[17] appears on the left. Mol wt standards are shown on the right. All immunoprecipitates were run under identical reducing conditions.

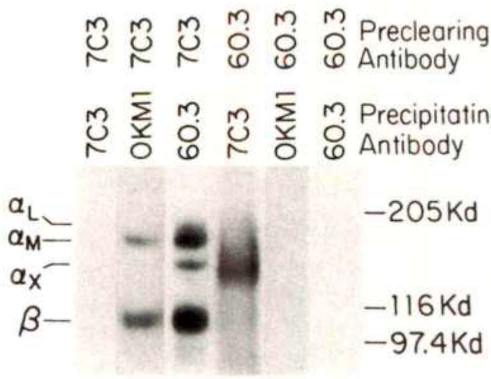

Fig 5. Immunoprecipitation experiments involving the three MAb. ^{125}I-Granulocyte lysates were first immunoprecipitated with the designated "pre-clearing antibody" before immunoprecipitation with the "precipitating antibody." The latter immunoprecipitates were subjected to SDS-7% PAGE. The α_L, α_M, α_X, and β-subunit designation appears on the left. Mol wt standards are shown on the right.

the cell. Antibody 60.3 demonstrated immediate, profound inhibition of the neutrophil oxidative response to C3bi-coated particles that could be reversed after removal of the antibody. Antibody 7C3 demonstrated a time-dependent, largely irreversible inhibition of the neutrophil oxidative response to opsonized zymosan that correlated with capping of the bound antibody. Antibody OKM1 had little effect on PMN respiratory burst activity in response to zymosan. Most striking was the observation that all three antigens recognized by these antibodies demonstrated the capacity for up-regulation after stimulation, although cellular responsiveness was not similarly restored.

The specificity of these antibodies for the active site of the C3bi receptor could be inferred from the results of these studies. Antibody 60.3 had an immediate effect on both particle adherence and O_2^- generation, suggesting that this antibody binds to an epitope close to the active site of the C3bi receptor. Conversely, antibody 7C3 affected these two functions in a time-dependent manner, suggesting that some post-binding step mediated the inhibitory effects of this antibody. The correlation of 7C3's effects with the marked capping of the antibody suggests that the neutrophil may undergo structural alterations after 7C3 binding that, with time, leave the cell less capable of functional responses. Finally, under our conditions, antibody OKM1 seemed to bind an epitope distinct from the active site of the C3bi receptor. Neither O_2^- generation nor particle adherence was markedly inhibited by this antibody, in agreement with previous findings that demonstrated only minimal inhibition of the binding or uptake of EC3bi to PMNs by OKM1.[20]

The functional defects induced by these MAb appeared to be unrelated to the kinetics of antibody binding or the number of antigen binding sites. All three MAb bound in a rapid and saturable manner. Furthermore, the number of antigen binding sites was comparable for MAb 60.3 and 7C3.

Klebanoff et al have reported that the binding of C3bi-coated erythrocytes to PMNs and monocytes is inhibited by treatment of these cells with antibody 60.3.[6,21] Phagocytosis of serum-opsonized zymosan and myeloperoxidase-mediated protein iodination were also inhibited. In the present studies, we have confirmed the ability of antibody 60.3 to inhibit binding of opsonized zymosan by PMNs as assessed both microscopically and by flow cytometry, and by the subsequent triggering of O_2^- release.

It is unlikely that 7C3 binds directly to the active site of the C3bi receptor, since (a) both C3b- and C3bi-coated erythrocytes exhibit decreased binding to 7C3-treated PMNs (54% and 64% of control, respectively[3]) and (b) the inhibitory effects of 7C3 on particle adherence and O_2^- generation were not immediate. Rather, the interference of C3bi-mediated triggering by 7C3 may be due to changes in the distribution of PMN membrane receptors induced by capping of the CR3 complex, an observation first noted by Melnick et al[4] and confirmed here. Of note, the capping of MAb 7C3 and its antigen did not result in co-capping of the OKM1 or 60.3 antigen. The effects of 7C3 on cell attachment and internalization were not as profound as those seen using antibody 60.3 and, consistent with previous studies,[3] suggested a significant postbinding effect in the ability of 7C3 to interfere with O_2^- generation.

The antigens detected by these three antibodies—OKM1, 60.3, and 7C3—appear to belong to a family of structurally related leukocyte surface glycoproteins. Each has a distinct, higher mol wt α-subunit that is noncovalently associated with a common β-subunit.[22] These α-subunits have been designated α_L (a 180-kd glycoprotein detected by the LFA series of MAb[23]), α_M (a 170-kd glycoprotein detected by anti-Mac-1,[24-26] anti-Mol,[27,28] and OKM1[7]), and α_X (a 150-kd glycoprotein reactive with anti-Leu M5 MAb[29]). The variability in the reported mol wt may be related to the degree of glycosylation of the antigens.

Antibodies OKM1,[7] anti-Mac-1,[24-26] and anti-Mol[27,28] all immunoprecipitate the same mol wt heterodimer. Immunoblotting experiments have demonstrated that these antibodies bind to the α_M-subunit and coprecipitate the β-chain because of its noncovalent association with the α_M-chain.[22] Because these three antibodies do not competitively block the binding of one another, they identify distinct epitopes on an identical antigen. This α_M-subunit is present on PMNs, monocytes, and natural killer cells, but not on lymphocytes.[25,26,28] The relative mol wt of the OKM1 antigen reported here (Fig 4) is consistent with that described in previous studies. Although studies to date using both normal cells[20] and cells from patients genetically deficient in this antigen[30] indicate that OKM1 precipitates the C3bi receptor, the data reported here suggest that OKM1 does not bind to the active site of the receptor.

Antibody 60.3 appears to be closely related to MAb TS1/18, which binds to the β-subunit shared by α_L, α_M, and α_X.[22] This presumptive binding site may explain (a) why these two antibodies bind to lymphocytes in addition to PMNs, monocytes, and natural killer cells, and (b) why both antibodies immunoprecipitate all three α-chains and the common β-chain from cell lysates (Fig 4).[5,22,23] Binding to this site is consistent with the ability of antibody 60.3 to remove the OKM1 antigen from PMN cell lysates (Fig 5).

These experiments indicated that the 60.3 antibody coprecipitated the same α_M antigen detected by OKM1.

Antibody 7C3 apparently binds to an antigen associated with this family of leukocyte differentiation antigens, since it immunoprecipitates α_M and β-chains similar to 60.3 and OKM1 (Fig 4). However, the presumptive binding site of 7C3 resides in an antigen of approximate mol wt of 130-kd that is loosely associated with this complex. After preclearing with antibody 7C3, 60.3 immunoprecipitates all four antigens from the cell lysate (Fig 5). However, preclearing with 60.3 removes all 7C3 antigen except the 130-kd moiety (Fig 5). Thus this 130-kd antigen must be loosely associated with the α_M and β-chains. Alternatively, 7C3 could bind to an epitope shared by the three antigens.

Consistent with their shared antigenic similarity, the 60.3, OKM1, and 7C3 antigens are rapidly up-regulated under specific conditions. Although some of the apparent "up-regulation" of antigen undoubtedly represented loss of surface antibody, the degree of up-regulation exceeded that which could be explained by simple dissociation of antibody from cell surface antigens. By indirect immunofluorescence, approximately 50% of 7C3, 35% of OKM1, and 20% of 60.3 was shed during warming at 37 °C over 30 minutes. Such shedding could account for the newly detected sites observed with warming of antibody-saturated cells (Fig 3) but could not account for the extent of up-regulation after membrane stimulation. Under the latter conditions, cells bound 150% to 220% of the amounts of antibody bound to unstimulated cells. These studies did not address whether shed antibody was displaced as antigen–antibody complexes or as antibody alone. It is unlikely that antibodies were internalized by the cell, since experiments using ^{125}I-labeled antibodies paralleled the results with FITC-labeled antibodies.

The factors modulating receptor up-regulation are incompletely defined, although all share membrane perturbation or receptor ligand interaction.[31,32] The α_M antigen (Mol-α antigen) has been identified in a cytoplasmic granular fraction of neutrophils, as well as in the plasma membrane.[33] Degranulation of the cell results in translocation of new antigen to the plasma membrane and a marked increase in the expression of surface antigen.[33] It seems likely that the antigens detected by OKM1, 60.3, and 7C3 undergo similar translocation from cytoplasmic granule stores. Of interest, however, was the finding that the up-regulation of 7C3 antigen was not associated with complete cellular recovery as assessed by subsequent O_2^- generation by opsonized zymosan. As noted above, this may reflect significant postbinding effects on cells preincubated with 7C3.

These experiments demonstrate that MAb binding at similar sites on the neutrophil may have markedly different functional effects. The specific antibody binding site as well as conditions of incubation, temperature, and cell activation all may play significant and distinct roles in determining the final observed functional effect of antibodies on cells. Such conditions should be carefully assessed in future studies of the effects of MAb on cellular physiology.

ACKNOWLEDGMENT

We thank Dr Harry Malech for helpful discussions and for providing us with MAb 31D8 and 7C3, Wendy Sullivan for technical assistance, and Sheila Day and Lynn Guthrie for assistance in manuscript preparation.

Abnormal In Vitro Proliferation and Differentiation of T Colony-Forming Cells in Patients With Lymphadenopathy Syndrome

By Yanto Lunardi-Iskandar, Vassilis Georgoulias, Willy Rozenbaum, David Klatzmann, Marc Cavaille Coll, Patrice Meyer, Marc Gentilini, Jean Claude Gluckman, and Claude Jasmin

Patients with acquired immunodeficiency syndrome (AIDS) present impaired colony growth and in vitro differentiation capacity of peripheral blood and bone marrow T colony-forming cells (T-CFC). We show that peripheral blood, bone marrow, and lymph node T-CFC from patients with persistent lymphadenopathy syndrome (LAS), a syndrome that can precede AIDS, displayed similar abnormalities. Indeed, peripheral blood T-CFC generated a low number of colonies in seven out of 12 patients, and almost no colonies were obtained from bone marrow cells of all patients. The simultaneous study of T-CFC from peripheral blood and lymph node mononuclear cells seems to provide a reliable indicator for the risk of developing AIDS. The six patients who developed AIDS displayed extremely low numbers of peripheral blood T-CFC (13 ± 17 colonies per 5 × 10^4 cells), and in two of them, no colonies could be obtained from lymph node T-CFC. The remaining patients who had not developed AIDS displayed a higher number of peripheral blood T-CFC (141 ± 113 per 5 × 10^4 cells) and lymph node T-CFC, which, in addition, preserved their clonogenic capacity. In some patients, peripheral blood and lymph node, but not bone marrow, T-CFC were capable of generating colonies in the absence of added growth factors or mitogens, whereas in others, colony formation was obtained with purified interleukin 2 (IL 2) alone. Both spontaneous and IL 2-induced colony formation was abrogated by a monoclonal antibody against the IL 2 receptor. Taken together, these findings suggest that at least some T-CFC expressed IL 2 receptors. Colonies generated either in the presence or in the absence of added growth factors were composed of T4$^+$, T6$^+$, and T8$^+$ cells, indicating impaired in vitro T-CFC differentiation. These findings indicate that a dramatic quantitative and qualitative impairment of the proliferation and differentiation of peripheral blood and lymph node T-CFC precedes the clinical evolution from LAS to AIDS.

A NUMBER OF ASSAYS for the growth of T cell colonies in semisolid media have been developed[1–5] to detect and study the differentiation capacity of peripheral blood and bone marrow T colony-forming cells (T-CFC) in normal subjects[6–8] and in patients with a variety of pathological conditions.[9–11]

In normal subjects, T-CFC have either an immature (E^-, $T3^-$) phenotype (displaying neither receptors for sheep erythrocytes nor T3 molecule) or presumably mature (E^+, $T3^+$) phenotype.[7,8] T cell colony growth from peripheral blood and bone marrow T-CFC requires stimulation with phytohemagglutinin (PHA) or the addition of interleukin 2 (IL 2)-containing conditioned medium to the cultures.[2,7,8] Colonies comprise mature T cells bearing mainly the T3$^+$ and T4$^+$ surface phenotypes,[7,8] but some T3$^+$ and T8$^+$ cells have also been detected.[12]

The lymphadenopathy syndrome (LAS) is defined as a syndrome of unexplained lymphadenopathy of more than three months' duration at two or more extra-inguinal sites.[13–16] Many patients manifest nonspecific symptoms (weight loss, oral thrush, diarrhea, unexplained fever), and prospective epidemiological studies[17] suggest that about 10% of patients will ultimately develop either opportunistic infections or Kaposi's sarcoma, which characterizes the acquired immunodeficiency syndrome (AIDS).[18] Moreover, LAS and AIDS patients present low number of T lymphocytes, especially the T4$^+$ subset, and qualitative abnormalities of the immune system (decreased proliferative responses to mitogens, allo- and auto-antigens, lack of T cell help for immunoglobulin synthesis, and decreased production of IL 2 by lymphocytes).[13–16,19,20] PHA-induced colony formation from peripheral blood T-CFC from LAS and AIDS patients[21] and in hemophiliacs with lymphadenopathy[22] showed impaired colony growth capacity, which could be restored with exogenous IL 2. We have recently reported that the colony-forming capacity of peripheral blood and bone marrow T-CFC from AIDS patients was significantly impaired.[23] Moreover, the patients' T-CFC displayed extremely low self-renewal capacity. Interestingly, T cell colonies were composed, unlike normal colonies, of relatively immature cells bearing the T6$^+$, T4$^+$, T8$^+$.[23] In the present study, we raised the question whether peripheral blood, bone marrow, and lymph node T-CFC of LAS patients show similar abnormal in vitro proliferation and differentiation capacities. The results indicate that patients' peripheral blood and bone marrow T-CFC displayed impaired proliferative capacities, which were more pronounced in patients who subsequently developed AIDS. Conversely, lymph node T-CFC of LAS patients who did not develop AIDS were more clonogenic than the T-CFC of patients who progressed to AIDS. In addition, peripheral blood and lymph node T-CFC showed impaired in vitro differentiation, similar to that observed in AIDS patients.[23]

MATERIALS AND METHODS

Patients. Heparinized peripheral blood, bone marrow, or lymph node biopsy specimens were obtained from 19 consecutive patients

with LAS. All but two patients, a Haitian woman (No. 16) and an intravenous drug user (No. 4), were male homosexuals All patients fulfilled the LAS criteria.[16] One patient (No. 15) presented with general symptoms, two (No. 2 and No. 17) had syphilis, and one (No. 14) had zoster (Table 1). Cytologic studies of lymph node biopsy sections revealed no evidence of malignant disease and were compatible with the diagnosis of LAS.[24] Six patients (14 through 19) developed AIDS within a year (three to 12 months) after T-CFC investigation. All patients were studied on presentation, before any treatment was applied, and displayed serum antibodies against the lymphadenopathy-associated virus (LAV) as detected by enzyme-linked immunosorbent assay[17] and Western blot.[25] Seven clinically healthy male homosexuals and 17 healthy heterosexuals were also studied as controls. All healthy male homosexuals but one, as well as all healthy heterosexuals, were seronegative for LAV antibodies.[23] Informed consent for these studies was obtained from all patients.

Cell separation. Peripheral blood mononuclear cells (PBMCs) and bone marrow mononuclear cells (BMMCs) were obtained by Ficoll-Paque (Pharmacia Fine Chemicals, Uppsala, Sweden) density-gradient centrifugation ($d = 1.077$ g/cm^3). Interface cells were washed twice with Hanks' balanced salt solution (HBSS; Inst Pasteur Production, Marnes-la-Coquette, France) and resuspended (10^6 cells per milliliter) in growth medium (α-modified Eagle's medium [α-MEM]; GIBCO, Grand Island, NY). Lymph node biopsy specimens were mechanically dissociated, cells were suspended in HBSS, and lymph node mononuclear cells (LNMCs) were obtained by density centrifugation as described earlier. Their viability, tested by trypan blue dye exclusion, was always >90%.

In some experiments, cells were further separated on the basis of sheep red blood cell (SRBC)-rosette formation with AET (2-amino ethylisothiouronium hydrobromide; Sigma Chemical Co, St Louis)-treated SRBCs[26] and a second density-gradient centrifugation Interface cells were thereafter treated with OKT3 monoclonal antibody (MoAb) (Ortho, Raritan, NJ) (50 μL/10^6 cells in a final dilution 1:400 vol/vol, at 4 °C) and pretested low Tox-H rabbit complement (Cedarlane, Ontario; 70 to 90 μL/10^6 cells in a final dilution 1·8 vol/vol) at 37 °C. This cell fraction contained less than 2% E$^+$ and no OKT3$^+$ cells and will be referred to as E$^-$OKT3$^-$ cells. E$^+$ cells were obtained from the pellet of the second density centrifugation after hypotonic lysis of the SRBCs. Their viability, tested by trypan blue dye exclusion, was >90%.

T cell colony assay. Mononuclear cells (5×10^5 cells per milliliter) or cell fractions were seeded in 0.8% methylcellulose (Fluka, Bachts, Switzerland) in α-MEM supplemented with 20% (vol/vol) heat-inactivated fetal calf serum (FCS; GIBCO), 2 mmol/L-glutamine and antibiotics, in the presence and the absence of 20% (vol/vol) PHA-leukocyte conditioned medium. This conditioned medium (PHA-LCM) was a seven-day supernatant from PHA (PHA-M 1%, vol/vol, DIFCO Lab, Detroit)-stimulated normal PBMCs (10^6 cells per milliliter in α-MEM supplemented with 10% FCS and 2 mmol/L L-glutamine) and contained 0.2 U/mL of IL 2 (1 U = 50 BRMP U) activity when tested on an IL 2-dependent human T cell line.[27] In addition, cells were seeded in the presence of 0.3 U/mL of PHA-free semipurified IL 2. This was obtained from 48-hour supernatants of PHA-M (1%, vol/vol)–stimulated normal PBMCs, precipitated with ammonium sulfate, filtered on Sephadex G 75 superfine columns (Pharmacia), and represented the pooled 15-kd to 22-kd fractions that contained the IL 2 activity (5 U/mL). PHA-free IL 2 could not induce cell proliferation or colony formation from normal PBMCs in the absence of PHA (kindly provided by Dr F. Triebel, UER Pitie Salpetriere, Paris).[8,28] One tenth milliliter of the methylcellulose-containing cell preparation was seeded per well in 96-well flat-bottomed microtest plates (Nunc, Roskilde, Denmark). Cultures were incubated for five to seven days at 37 °C in 5% CO^2 in air, and aggregates containing more than 50 cells were counted as colonies under an inverted microscope.

In some experiments, 5×10^5 cells per milliliter were incubated for 45 minutes at 37 °C with increasing concentrations (10^{-3} to 10^{-7}; vol/vol) of anti-Tac monoclonal antibody, which recognizes the IL 2 receptor (IL 2-R; anti-Tac kindly provided by Dr TA Waldmann,

National Institutes of Health).[29] The cells were washed extensively and seeded in methylcellulose in the absence or presence of IL 2 as described.

Clonogenic capacity of T-CFC. The clonogenic capacity of T-CFC from PBMCs and LNMCs was determined by incubating 10^6 cells per milliliter in growth medium supplemented with 10% FCS and 2 mmol/L L-glutamine for three to five days. Extensively washed cells were seeded in methylcellulose (5×10^5 viable cells per milliliter), in either the presence or the absence of added growth factors as described ("delayed plating").[30]

Phenotypic characterization of PBMCs, BMMCs, LNMCs, and colony cells PBMCs, BMMCs, LNMCs were phenotyped using a panel of monoclonal antibodies, including the OKT series (Ortho); the T11 (Coultronics, Margency, France), which recognizes SRBC receptors; and an anti-HLA–class II (BM-50; kindly provided by Dr D. Charron, UER Pitie Salpetriere, Paris). Positive cells were counted with an Ortho Spectrum III Analyser, using a minimum sample size of 2,000 cells.

Colonies of the same size and morphology were individually picked, pooled, dissociated, and washed with HBSS. Colony cells were resuspended in phosphate-buffered saline supplemented with 0.01% sodium azide and 2% FCS, and phenotyped by indirect immunofluorescence using the OKT series monoclonal antibodies Nonspecific immunofluorescence was always <5%. At least 50 to 100 cells were evaluated for each determination

Statistical analysis Statistical comparison of the mean values was performed using the Student's *t* test.

RESULTS

PBMC, BMMC, and LNMC phenotypes. As expected, $T4^+$ cells were decreased (range, 1% to 43%), while $T8^+$ cells ranged from 25% to 73% (Table 1). All patients displayed, to varying degrees, a low $T4^+$:$T8^+$ ratio (range, 0.02 to 1.16; normal values, 1.5 to 2.3). Patients who subsequently developed AIDS (14 through 19) had a significantly lower $T4^+$:$T8^+$ ratio than the remaining patients (mean ± SD:0.27 ± 0.21 *v* 0.23 ± 0.17, respectively; $P < .05$). In these patients, both the proportion and the absolute number of $T4^+$ (13.7% ± 7.4% and 198 ± 102 cells per cm^3, respectively) were lower than in those who did not develop AIDS (26.1% ± 6.5% and 483 ± 226 cells per cm^3, respectively). Tac^+ cells were always <5%.

Phenotypic characterization of BMMCs showed no significant peripheral blood contamination as evaluated by the proportion of $T3^+$ and $T11^+$ cells, except in two patients (No. 3 and No. 4, respectively; Table 1). No $T6^+$ cells were found in any patient, whereas Tac^+ cells were ranged between 0% and 9% (Table 1).

Phenotypic characterization of LNMCs showed 9% to 46% $T3^+$ cells (mean ± SD:32.3% ± 12%; Table 1) and in four of them (1, 4, 6, 9), $T4^+$ cells were less than 10%. $T8^+$ cells were usually <30%, and the $T4^+$:$T8^+$ ratio ranged from 0 to 1.2. In two patients (No. 5 and No. 9; Table 1), 23% and 28% of the LNMCs were Tac^+, respectively.

T cell colony formation. PBMCs from seven out of 12 patients generated low numbers of colonies (less than 50 colonies/5×10^4 cells). The colony formation from patients who did not develop AIDS was lower than in normal heterosexuals (mean ± SD, 141 ± 113 and 370 ± 179 colonies/5×10^4 cells, respectively; $P < .001$). Patients who subsequently developed AIDS generated a dramatically decreased number of colonies (13 ± 17 colonies/5×10^4 cells) (Table 2). There was no correlation between the absolute number of $T4^+$ cells and the number of colonies. Furthermore, T cell colony growth from seven clinically healthy male homosexuals who were at risk of developing AIDS (described in detail elsewhere[23]) was also significantly decreased (208 ± 46 colonies/5×10^4 cells; $P < .01$).

Bone marrow T-CFC could not generate colonies, irrespective of the subsequent development of AIDS. Conversely, in six out of eight patients who did not develop AIDS, lymph node T-CFC yielded a relatively high number of colonies (more than 100 colonies/5×10^4 cells). This contrasts with the absence of colony growth from LNMCs of patients No. 18 and No. 19 and the 24 colonies obtained from patient No. 14 (Table 2), who subsequently developed AIDS.

To determine more precisely the clonogenic capacity of presumably "mature" and immature T-CFC,[8] fractionated E^+ and E^- $T3^-$ PBMCs and LNMCs were also tested for T cell colony growth. As shown in Table 3, peripheral blood E^+ and E^- $T3^-$ cells (except in one patient) were unable to generate colonies, although colony growth could be obtained from unfractionated PBMCs, suggesting that cellular cooperation(s) are important for T cell colony growth. Lymph node E^+ cells from two patients (No. 8 and No. 18; Table 3)

Unfractionated MNC, E$^+$, and E OKT$_3$/ (5 × 10^6/mL) were seeded in methylcellulose in the presence of PHA-LCM, as described in Materials and Methods. Aggregates containing more than 50 cells were counted as colonies. Results as expressed as mean number of colonies ± SD/5 × 10^4 seeded cells from triplicate cultures. ND, not done.

*Patients who subsequently developed AIDS.

generated a high number of colonies, but E-T3$^-$ cells did not. It is noteworthy that in patient No. 18, who subsequently developed AIDS, unfractionated LNMCs did not generate colonies, whereas E$^+$ cells did.

Colony formation in the absence of added growth factors and in the presence of purified IL 2. Both unfractionated PBMCs (in four out of 11 patients) and LNMCs (in four out of 11 patients) generated colonies in the absence of added growth factors or mitogenic stimulation (Table 4). To determine whether IL 2-R were involved in this spontaneous colony growth, cultures were performed after incubating cells with anti-Tac MoAb. As shown in Fig 1, spontaneous colony formation could be abrogated with anti-Tac MoAb, irrespective of the source of the cells. Low amounts (10^6 vol/vol) of anti-Tac inhibited the colony formation in all cases.

Table 4. Spontaneous and IL 2-Induced T Cell Colony Formation

Patient No.	Source of Cells	Spontaneous	IL 2
1	PBMC	64 ± 9	503 ± 37

19*	LNMC	0	0

PBMCs and LNMCs (5 × 10^5/mL) were seeded in methylcellulose in the absence or presence of added IL 2 without mitogenic stimulation and incubated as described in Materials and Methods. Results are expressed as mean ± SD of colonies per 5 × 10^4 seeded cells from triplicate cultures.

*Patients who subsequently developed AIDS.

Biochemically purified IL 2 induced colony growth from PBMCs and LNMCs in two and three patients (1 and 2 and 7 through 9; Table 4), respectively, without previous mitogenic stimulation. Similar results were obtained when, in some experiments, genetically recombinant (Biogen, Geneva, Switzerland) IL 2 was substituted for biochemically semipurified IL 2 (not shown). Because the induction of colony formation with purified IL 2 seems to indicate that some T-CFC could express IL 2-R,[31] both PBMCs and LNMCs were incubated with anti-Tac MoAb before seeding in the presence of IL 2. As shown in Fig 2, anti-Tac abrogated the IL 2-induced colony formation. Conversely, a pool of three anti-HLA–Class II MoAbs, used as control, could not modify the plating efficiency. It is worthy to note that semi-purified IL 2 inhibited T cell colony growth from PBMCs of two patients (No. 12 and No. 15; Table 4) and from LNMCs of three patients (1, 4, and 5; Table 4). Interestingly, BMMCs from seven patients (1 through 5 and 14 through 16) did not generate either spontaneous or IL 2-induced colonies, although in two of them (No. 3 and No. 16; Table 1) 7% and 9% of the cells, respectively, were Tac$^+$.

Phenotypic characterization of colonies. Colonies generated from PBMCs and LNMCs in the presence of PHA-

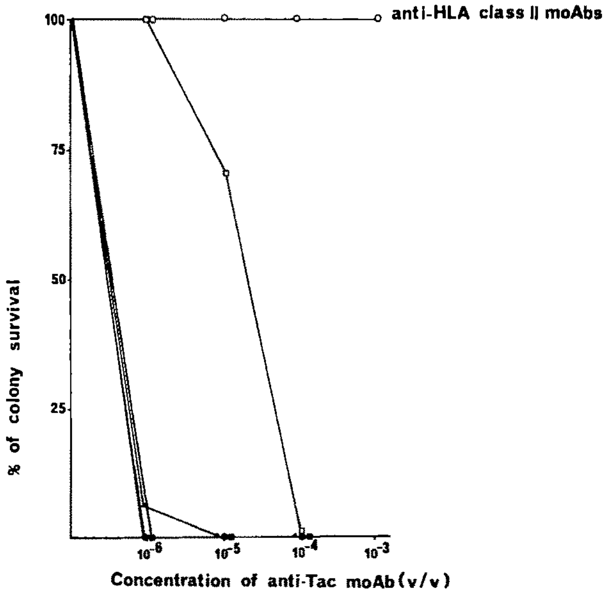

Fig 1. Inhibition of IL 2-induced T cell colony formation with anti-Tac MoAb. PBMCs or LNMCs (5 × 10^5 cells per milliliter) were incubated with increasing concentrations of either anti-Tac or a pool of three anti-HLA class II MoAbs at 37 °C for one hour. Extensively washed cells were seeded in methylcellulose in the presence of purified IL 2 as described in Materials and Methods. Each sign represents a different patient: ■—■, No. 1 (PBMC); ▲—▲, No. 2 (PBMC); □—□, No. 5 (PBMC); ●—●, No. 4 (LNMC).

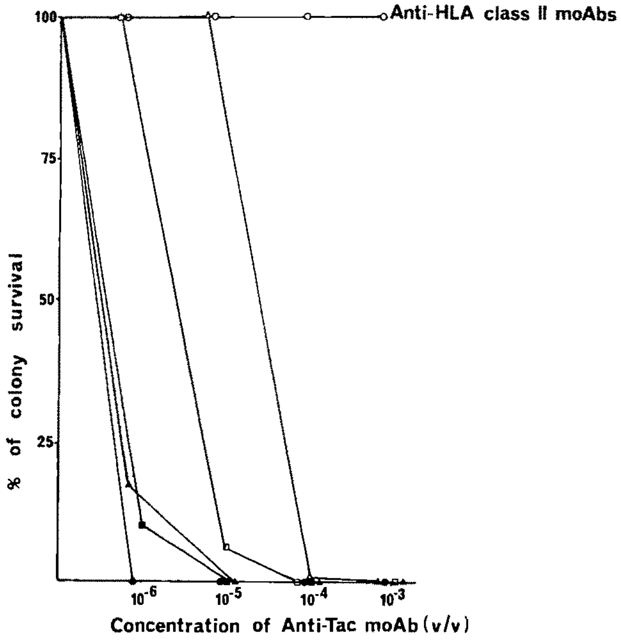

Fig 2. Inhibition of spontaneous T cell colony formation with anti-Tac MoAb. PBMCs or LNMCs (5×10^5 cells per milliliter) were incubated with increasing concentrations of either anti-Tac or a pool of three anti-HLA class II MoAbs at 37 °C for one hour. Extensively washed cells were seeded in methylcellulose in the absence of added growth factors and mitogenic stimulation as described in Materials and Methods. Each sign represents a different patient: ●—●, No. 1 (PBMC); ▲—▲, No. 2 (PBMC); △—△, No. 5 (LNMC); ■—■, No. 15 (PBMC); □—□, No. 4 (LNMC).

LCM were composed of lymphoblastoid cells bearing T cell surface markers (Table 5). Forty-eight percent to 83% of the colony cells were T3$^+$, whereas 46% to 94% were T4$^+$ and 58% to 95% were T8$^+$. In all but one case (No. 5; Table 5), more than 50% of the colony cells were T6$^+$, unlike T cell colonies from healthy heterosexuals. Moreover, induced colonies from clinically healthy male homosexuals contained a significantly higher proportion of T6$^+$ cells than colonies from normal heterosexuals ($P < .001$; Table 5).[23]

Spontaneous colonies from PBMCs and LNMCs were smaller than induced colonies (up to 100 cells per colony), and were composed of lymphoblastoid cells bearing T cell surface markers (Table 5). The phenotype of cells from spontaneous colonies was not significantly different from that of induced colonies.

Clonogenic capacity of T-CFC. The proliferative capacity of peripheral blood, bone marrow, or lymph node T-CFC was also tested after incubating the cells in liquid culture for three to five days in the absence of added growth factors or mitogens before seeding in methyl cellulose. This "delayed" plating has been proposed as a measure of the proliferative capacity of the clonogenic cells.[30] As shown in Table 6, "delayed" plating did not, in general, enhance the spontaneous plating efficiency and in two of three patients (No. 1 and No. 2; Table 6), completely abrogated the induced colony growth. However, delayed plating of LNMCs from patient No. 18, who subsequently developed AIDS, significantly enhanced the induced colony formation (Table 6). Colonies obtained by "delayed" plating were also of T cell origin, since they were counted of more than 75% T3$^+$ cells.

DISCUSSION

The results reported here indicate that LAS patients present important quantitative and qualitative abnormalities of peripheral blood and bone marrow T-CFC. The bone marrow T-CFC from all patients failed to generate colonies and the peripheral blood T-CFC of several patients, especially those who subsequently developed AIDS, gave rise to a particularly low number of colonies. Similarly, other investigators showed impaired T colony formation from PBMCs of hemophiliacs with lymphadenopathy[22] and AIDS and of LAS patients.[21] However, in these studies,[21,22] T cell colony formation was obtained by PHA stimulation of patients' PBMCs without the addition of IL 2; exogenous IL 2 enhanced the colony growth, suggesting that the observed low plating efficiency could be due to the impaired capacity of patients' T cells to produce IL 2.[20]

In our experiments, colony formation was induced with crude conditioned medium containing both IL 2 and low amounts of PHA (0.001%). Contaminant PHA could not yield colony growth, whereas as little as 0.1 U/mL of IL 2 is sufficient for normal T cell colony formation in the presence of PHA.[8] Moreover, aggregates containing more than 50 cells were considered as colonies, whereas in the abovementioned studies,[21,22] aggregates with as few as 25 cells

Table 5. Phenotypic Characterization of Induced and Spontaneous T Cell Colonies From PBMCs, BMMCs, and LNMCs of LAS Patients

Patient No	Source of Cells	Induced Colonies (%)				Spontaneous Colonies (%)			
		T3	T4	T6	T8	T3	T4	T6	T8
1	PBMC	48	46	56	60	42	40	38	41
2	PBMC	81	88	92	94	80	82	84	87
4	LNMC	83	79	65	83	100	88	92	94
5	LNMC	69	87	34	58	62	50	41	54
Healthy homosexuals (n = 3)	PBMC	79 ± 9	60 ± 11*	50 ± 14*	48 ± 15*	NCG			
Healthy heterosexuals (n = 7)	PBMC	75 ± 5	47 ± 13	17 ± 5	35 ± 4	NCG			

Individually picked colonies were pooled, washed, and dissociated, and colony cells were stained by indirect immunofluorescence with the corresponding MoAb. NCG, no colony growth

$^*P < .01$ (Student's *t* test).

Table 6. Clonogenic Capacity of LAS Patients' T-CFC

Patient No	Source of Cells	Immediate Plating		Delayed Plating•

18•	LNMC	0	0	0	236 ± 26

•Cells (5×10^5/mL) were seeded in methylcellulose after 72 hours of cell incubation in α-MEM in the absence of added growth factors or mitogens. Results are expressed as mean number of colonies per 5×10^4 seeded cells from triplicate culture.

•Patients who subsequently developed AIDS

counted as colonies. It is likely that the two culture conditions allow the growth of distinct T-CFC subsets and could explain our observation that IL 2-containing conditioned medium did not enhance the plating efficiency.

Lymph node T-CFC gave rise to a high number of colonies in seven out of eight LAS patients who had not progressed to AIDS and a low number in three patients who subsequently developed AIDS. This observation could be of prognostic importance, since all patients who developed AIDS also yielded an extremely low T cell colony formation from peripheral blood cells. This group of patients could represent an earlier stage during the evolution of the disease, in which T cell precursors are still present in lymph nodes but not in peripheral blood.

In AIDS patients the absolute number of peripheral blood T-CFC was significantly correlated with that of $T4^+$ cells.[23] In the present study no such correlation could be established, suggesting that the low colony formation of peripheral blood T-CFC in LAS patients could precede the $T4^+$ lymphopenia. Moreover, although LAS patients who developed AIDS displayed significantly lower $T4^+$ cells than those who did not develop the full-blown disease, there was an important overlap of the $T4^+$ cell values, making any close correlation between this parameter and the outcome of the patients difficult. Therefore, it seems that the combination of low colony growth of both peripheral blood and lymph node T-CFC of LAS patients has a higher prognostic value than the absolute number of $T4^+$ cells. Recent studies also point out that other immunologic parameters, such as the 2-microglobulin,[31] mitogen-induced lymphocyte stimulation,[32] acid labile interferon,[33] could also be of prognostic value for the evolution of AIDS. It may be essential to determine whether early treatment of these particular patients could prevent or delay the development of AIDS.

In most patients, neither purified cell fractions, known to be capable of generating T cell colonies,[7,8] nor "delayed" plating, considered to be a method of measuring the clonogenic capacity of hematopoietic precursors,[30] could enhance the colony growth. However, in one patient (No. 18) who subsequently developed AIDS, purified lymph node E^+ cells but not unfractionated LNMCs generated colonies (Table 3). These observations suggest that, at least in this patient, inhibitory mechanism(s) could account for the low plating efficiency from LNMCs. Moreover, in patient No. 4, "delayed" plating of LNMCs revealed that T-CFC also displayed a high clonogenic capacity.

The fact that, in some patients, colony growth could be obtained either spontaneously or with biochemically purified and recombinant IL 2, whereas the anti-Tac MoAb abrogated colony formation, indicates that some T-CFC (both lymph node and peripheral blood) are already activated cells bearing IL 2-R.[34,35] The detected low proportion of Tac^+ cells does not contradict this finding, since T-CFC represent a small subset of T cells (usually two to three clonogenic cells per 10^3 PBMCs[8]). A similar phenomenon has been observed in some human malignant T cell lines[36] and in T-CFC from some patients with T cell malignancies.[9] Conversely, the fact that BMMCs in some cases did not generate IL 2-induced colonies although they expressed IL 2-R, suggests that IL 2-R were either not functional or displayed a low affinity for IL 2.[34] Thus the presence of activated T-CFC can probably explain the T cell colony formation in the absence of added growth factors.

In some patients, both biochemically purified and recombinant (not shown) IL 2 inhibited spontaneous colony formation. Although the reasons for this phenomenon are not yet known, we cannot exclude the possibility that IL 2 stimulated suppressor T cells to produce inhibitory activity(ies) for the proliferation of T-CFC.

Unlike colonies from healthy heterosexuals, colonies generated from LAS patients comprised mainly immature cells, bearing the $T4^+$, $T6^+$, $T8^+$ phenotype. The possibility that some colonies comprised mature ($T3^+$, $T4^+$, $T6^-$ or $T3^+$, $T8^+$, $T6^-$) cells cannot be excluded, since pooled colonies were used for phenotypic studies. However, the phenotype of spontaneous and induced colony cells was similar, indicating that the abnormal in vitro differentiation of peripheral blood, bone marrow, or lymph node T-CFC is growth factor independent.

In conclusion, our data indicate that T cell lymphopenia observed in LAS as well as in AIDS patients[23] and in some male homosexuals could be the result of several mechanisms, such as impaired proliferative capacity and decreased number and abnormal in vitro differentiation of T-CFC. In addition, the in vitro study of T-CFC could identify some LAS patients presenting a low number of peripheral blood and lymph node T-CFC, whose risk of developing AIDS is extremely high. Longitudinal studies are in progress in order to verify the prognostic value of this observation.

T3 Surface Molecules on Adult T Cell Leukemia Cells Are Modulated In Vivo

By Masao Matsuoka, Toshio Hattori, Tohru Chosa, Hiroyuki Tsuda, Shigeki Kuwata, Mitsuaki Yoshida, Takashi Uchiyama, and Kiyoshi Takatsuki

Cells from eight patients with adult T cell leukemia (ATL) and from four patients with non-ATL were examined to see if the T3 antigen of these cells could be modulated in vitro. We found a low density of T3 antigen and the presence of Tac antigen on cells from all patients with ATL. The density of T3 antigen on non-ATL cells was normal, and Tac antigen was not detected. Modulation of T3 antigen and an increase in Tac antigen-positive cells occurred when cells from patients with T4 non-ATL were cultured with OKT3 monoclonal antibody (mAb). Those changes in T3 antigen density and the appearance of Tac antigen-bearing cells by OKT3 mAb were not so marked when ATL cells were used. But the modulation of T3 antigen and the increase in Tac antigen-bearing cells by OKT3 mAb were closely related in cells from six ATL patients. These findings suggest that T3 T cell antigen receptor complexes on ATL cells are not functionally "frozen" by leukemic changes and might be modulated in vivo. In addition, modulation of T3 surface antigen on ATL cells was not induced by cultivation with human T cell leukemia virus type I particles and envelope proteins obtained by gene technology.

ADULT T CELL LEUKEMIA (ATL) has been established as a distinct clinical entity associated with retrovirus infection.[1-4] The surface phenotype of ATL cells characterized by monoclonal antibodies (mAbs) is $T3^+T4^+$-$T8^-T11^+Tac^+$.[5] With improved biochemical characterization of antigens, the functions of antigens recognized by some mAbs have been defined. Tac antigen is known to recognize interleukin 2 (IL 2) receptors or closely associated molecules.[6,7] Reinherz et al[8-10] found that T3 antigen is associated with the T cell antigen receptor (Ti) because T3 mAb coimmunoprecipitated Ti antigen from alloantigen-specific cloned T cells; both T3 and Ti antigens were comodulated by OKT3, anti-Ti mAb, or alloantigens. Our recent analyses of ATL cells using a laser flow cytometry showed that the mean fluorescence intensity (MFI) of T3 antigen significantly decreased on ATL cells, although those of T4 and T11 were normal.[11] The low density of T3 antigen and the presence of Tac antigen on ATL cells are equivalent to the surface phenotype of normal T cells whose T3 antigen is modulated by OKT3 mAb. It is interesting to know whether T3 antigen on ATL cells can still be modulated in vitro or is "frozen" at a low level. If the former is the case, Tac antigen expression on ATL cells might be the secondary phenomenon of T3 antigen modulation. So we studied the modulation of T3 antigen and the induction of Tac antigen by OKT3 mAb simultaneously, using ATL cells from eight patients and malignant T cells from four non-ATL patients.

We also studied the effects of human T cell leukemia virus type 1 (HTLV-I) and envelope gene products of HTLV-I on T3 and Tac antigen expression of ATL cells in order to test whether low density of T3 antigen on ATL cells may be secondary phenomena of chronic stimulation of Ti molecules on ATL cells because these two molecules are noncovalently linked.[8-10]

MATERIALS AND METHODS

Reagents Fluorescein isothiocyanate (FITC)-conjugated OKT3, T4, and T8 mAbs and unlabeled OKT3, T4, and T8 mAbs were purchased from the Ortho Pharmaceutical Co (Raritan, NJ). FITC-conjugated anti-Tac mAb was generated as described elsewhere.[12] FITC-labeled goat $(Fab')_2$ antimouse $(Fab')_2$ fragments of immunoglobulin G (IgG) was from Cappel Laboratories (Cochranville, Pa). Affinity-purified FITC-labeled goat $(Fab')_2$ antihuman IgG was from Tago Inc (Burlingame, Calif). Concanavalin A (Con A) was from Pharmacia (Uppsala, Sweden) and phorbol 12-myristate 13-acetate (PMA) was from Consolidated Midland (Brewster, NY).

Cell culture and cell lines All cell cultures were done in complete medium, RPMI 1640 (Nissui, Tokyo) containing 10% fetal bovine serum (GIBCO, Grand Island, NY), 100 U/mL of penicillin, 100 μg/mL of streptomycin, and 2 mmol/L L-glutamine. Cell counts and viabilities were determined visually with trypan blue. The MT-2 cell line cells[13] were kindly provided from Dr I. Miyoshi (Kochi Medical University, Kochi, Japan). HUT 102 cell line cells[4] were from Dr R.C. Gallo (National Cancer Institute, Bethesda, Md). Peripheral blood mononuclear cells from patients and ten healthy donors (aged 26 through 38) were separated from heparinized blood by Ficoll-Conray density-gradient centrifugation. Normal T cells were purified by sheep red blood cell rosette-forming methods. After being washed three times with phosphate-buffered saline (PBS), cells were cultured with or without various reagents in a humid atmosphere with 5% CO_2 at 37 °C. For short-term culture, recombinant interleukin 2 (IL 2), which was kindly provided by Dr J. Hamuro (Ajinomoto Pharmaceutical, Yokohama, Japan), was used. Cells were fed with IL 2 (1 U/mL) every two days.

Patients Diagnoses of patients were based on accepted criteria for clinical, hematologic, and laboratory findings. Antibody to ATL virus-associated antigens (anti–ATLA-Ab) in the sera was measured by indirect immunofluorescence (IF) as described by Hinuma et al,[4] using MT-1 cells Antibodies to virus-associated cell surface membrane antigens (anti–MA-Ab) were also measured, using HUT 102 cells as described by Robert-Guroff et al.[14] Briefly 50 μL of 1:100 diluted patient's sera was added to 10^6 cells and incubated for 30 minutes on ice. After washing twice with PBS containing 1% bovine serum albumin (BSA) and 0.1% sodium azide (NaN_3), 50 μL

of FITC-conjugated affinity-purified antihuman IgG (1.40 dilution) was added. Cells were washed twice after another 30 minutes of incubation on ice and analyzed by a laser flow cytometry system (Spectrum III/Ortho Diagnostic Systems, Westwood, Mass) with exposure to a laser light of 488 mm at the intensity of 50 mW as described previously.[11] The results were expressed as the relative proportions of IF-positive cells Detection of human T cell leukemia/lymphotropic virus type I (HTLV-I) proviral DNA has been performed using a provirus clone, ATK-1, as a source of the probe.[15,16]

Isolation of HTLV-I particles and envelope protein of HTLV-I. HTLV-I particles were obtained from 2 L of culture medium of MT-2 cells as described by Yoshida et al[15] with a slight modification. Briefly, HTLV-I particles were obtained by centrifugation at 25,000 rpm for 90 minutes in a Hitachi RP 42 rotor after removing cell debris by low centrifugation (2,000 rpm for ten minutes). Crude HTLV-I particles were suspended in TNE buffer (20 mmol/L Tris HCl, pH 7.5/100 mmol/L NaCl/1 mmol/L EDTA), layered on a sucrose density gradient (20% to 60%), and centrifuged for 18 hours at 25,000 rpm in the rotor. For analysis of viral proteins, aliquots of each fraction were subjected to 15% polyacrylamide slab gel electrophoresis as described by Laemmli.[17] A low-molecular-weight kit from Pharmacia was used for molecular weight markers. Proteins were stained by silver staining methods. Fractions that contained virus proteins were collected, dialyzed against PBS, and stored at −70 °C until use. The concentration of virus is arbitrarily set as described below; 1 unit of virus per milliliter corresponds to 1.0 at 260 nm (A_{260}).

Envelope protein of HTLV-I was obtained by transforming *Escherichia coli* strain JK1046 with plasmid PEH9 The protein was purified as described previously.[18]

Cell surface marker analyses. Cell surface markers were analyzed by a laser flow cytometry system as described Malignant cells were cultured in 24-well tissue culture plates (Linbro Flow Lab, McLean, Va) at a concentration of 2×10^6 cells per milliliter in a total volume of 1 mL. OKT3 mAb (which was dialyzed against PBS for 18 hours at 4 °C), PMA, and Con A were added at various concentrations. After 18 hours of culture, T3 and Tac antigens were examined by indirect and direct IF methods.[11,12] For direct IF assay, the cutoff point was determined for each sample at which 0.5% of non-stained cells were positive, and the percentage of IF-positive cells was determined. Cells cultured with IL 2 were examined using the same system. The saturating amount of antibodies was determined using T8-positive chronic lymphocytic leukemia cells (T-CLL) for the OKT3 mAb indirect IF system and HUT 102 cells for the TAC mAb direct IF system.

RESULTS

Patients. Clinical profiles of the patients are presented in Table 1. Sera from all ATL patients were positive and those from non-ATL patients were negative for both anti–ATLA-Ab and anti–MA-Ab. Proviral DNA was demonstrated in all ATL cells and not detected in non-ATL cells. The diagnoses of chronic or acute ATL were based on clinical profiles as described elsewhere.[19] Surface phenotype analyses of cells immediately after cell separation showed that all ATL cells were T3$^+$, T4$^+$, T8$^-$, Tac$^+$; cells from patients MG, NB, and IT were T3$^+$, T4$^+$, T8$^-$, Tac$^-$; cells from patient ST were T3$^+$, T4$^-$, T8$^+$, Tac$^-$. The relative proportions of malignant cells in cell suspensions were assessed either by OKT4 or OKT8 mAb. More than 90% of cells from patients with ATL and T4 non-ATL reacted with OKT4 mAb, and 94% of cells from patient ST reacted with OKT8 mAb. The viability of cells immediately after cell separation was more than 95% and that of cultured cells was more than 90% except for cells cultured with PMA (10^{-8} mol/L); 62% to 90% of these were viable. Cell surface marker analyses of fresh cells are listed in Table 2. All ATL cells expressed Tac antigen and a low MFI of T3 antigen; however, apparent relationships between two markers were not observed. The proportions of all malignant cells bearing T3 antigen and the MFI of T3 antigen did not change significantly during culture for 18 hours in complete medium. The MFI of T3 antigen on ATL cells and on the other malignant cells was 29 to 56 and 77 to 95, respectively (Figs 1A, 2A, and 3A).

Modulation of T3 antigen and induction of Tac antigen of non-ATL cells. In the presence of OKT3 mAb (150 ng/mL), MFI of T3 antigen on normal cells decreased by 74% and those of non-ATL cells decreased by 28% to 54%, depending on the cells (Figs 1A and 4). The relative proportions of T3 antigen-bearing cells decreased by 74%, but those of non-ATL cells decreased only by 2% to 22% (Fig 1B). We also studied OKT4 or OKT8 mAb (150 ng/mL) to deter-

*Indicates reactivity to OKT8 mAb.

mine whether these mAbs modulated T3, T4, or T8 antigens, using T4 (from MG) and T8 (from ST) cells. Cells cultured with these mAbs did not change in reactivity with OKT3, OKT4, or OKT8 mAbs (data not shown). The effects of other mitogens on T3 antigen density were examined. Con A slightly decreased the MFI of T3 antigen on NB T4 cells and PMA markedly decreased those on all cells (Fig 1A). This phenomenon was also observed in cells from ST, in which 90% of the cells were viable after cultivation. The non-ATL cells did not express Tac antigen significantly (0% to 7%), even after cultivation with medium, and did express it after stimulation with OKT3 mAb, Con A, or PMA; and T8 leukemic cells expressed Tac antigen only in the presence of PMA (Figs 1B and 4). MFI and Tac antigen-positive cells also increased in the presence of mitogens used (Fig 1A). In general, the decrease in MFI of T3 antigen was well-correlated with the increase of relative proportions of Tac antigen-bearing cells. Cells cultured with HTLV-I did not change their reactivities to T3 and Tac mAbs at all.

Modulation of T3 antigen and expression of Tac antigen on ATL cells. The results of acute ATL and chronic ATL are shown in Figs 2 and 3, respectively. The changes in MFI of T3 antigen on ATL cells by OKT3 mAb were not as great as those of non-ATL cells (Figs 2A, 3A, and 4). In particular, cells from patient SW did not significantly decrease in MFI of T3 antigen when cultured with OKT3 mAb (Figs 2A and 4). The subtle changes in MFI of T3 antigen on ATL cells could not be attributed to contamination with normal T cells because cells from patient IH, whose peripheral blood leukocyte counts were highest and whose percentage of T4-bearing cells was 96%, had the greatest change in MFI of T3 antigen caused by OKT3 mAb (Fig 2A). In contrast to the non-ATL malignant T cells, changes in MFI of T3 antigen on ATL cells by Con A did not occur. The viabilities of ATL cells cultured with PMA (10^{-8} mol/L) were 62% to 82% and the percentage of Tac antigen-bearing cells decreased (Fig 2B), but MFI of Tac antigen-positive cells increased (Figs 2A and 3A). Tac antigen was expressed, to a variable extent, on all ATL cells immediately after cell separation, and the proportions of Tac antigen-positive cells increased after 18 hours of culture (Table 2, Figs 2B and 3B). The enhancement of ATL Tac antigen-bearing cells and increase in MFI of them by OKT3 mAb were also slight as compared with non-ATL but were evident. Cells from SW,

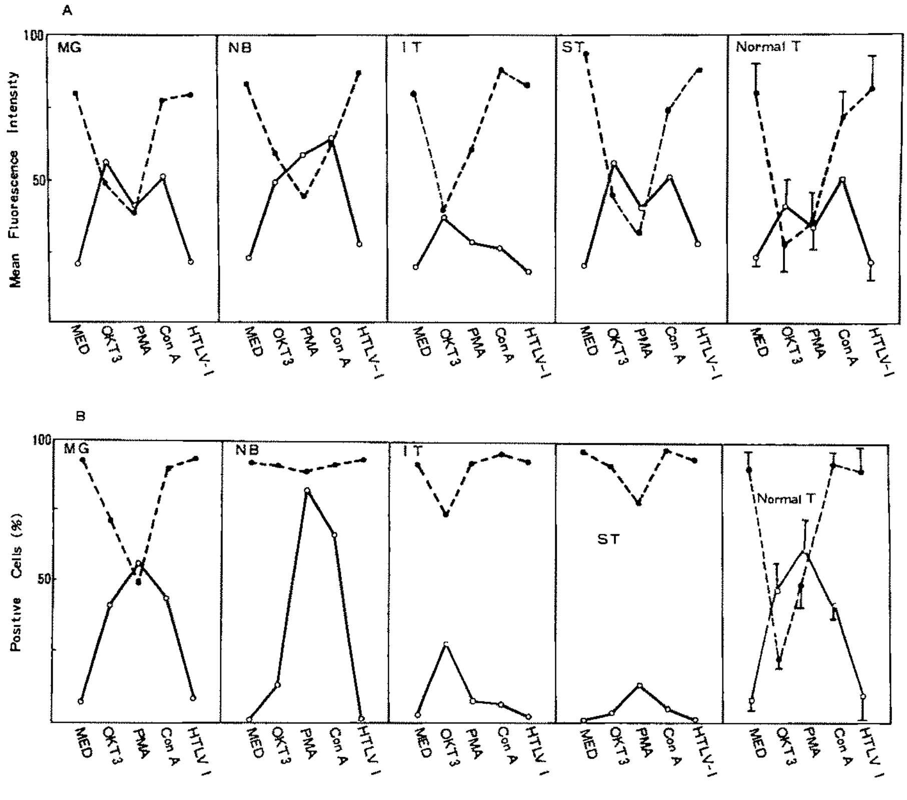

Fig 1. T3 and Tac antigen expression of non-ATL cells after cultivation with various agents. (A) Mean fluorescence intensity of T3 and Tac antigen. (B) Percentage of T3 and Tac antigen-positive cells. Cells were cultured with complete medium, and OKT3 mAb (150 μg/mL), Con A (4 μg/mL), or PMA (10^{-8} mol/L) for 18 hours. After cultivation, cells were stained with OKT3 or anti-Tac mAb and analyzed by flow cytometry. (●), T3 antigen; (O), Tac antigen.

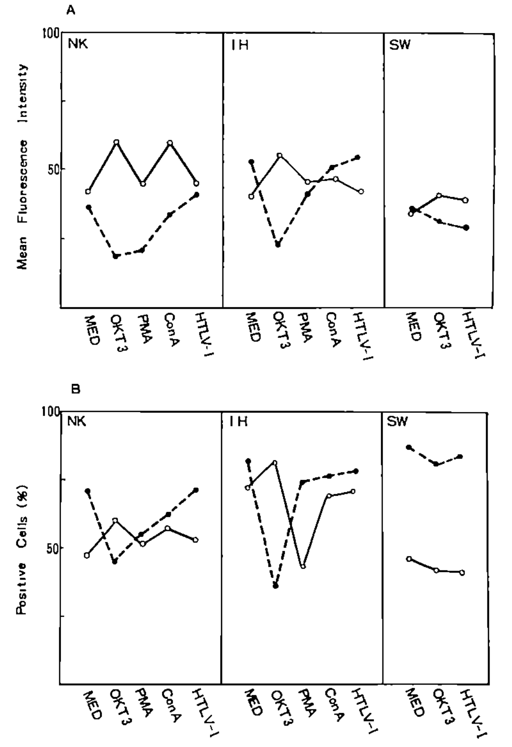

Fig 2. T3 and Tac antigen expression of ATL cells after cultivation with various agents. Mean fluorescence intensity (A) and percentage of antigen-positive cells (B) in acute ATL. (●), T3 antigen; (O), Tac antigen.

whose T3 antigen was not modulated by OKT3 mAb, again did not react with OKT3 mAb with respect to an increase in Tac antigen-bearing cells but, rather, MFI of Tac antigen decreased. T3 antigen on TI cells could be modulated by OKT3 mAb; however, the significant increase of Tac antigen-positive cells was not observed (Fig 3B). When the cells from six other patients whose T3 antigen was moderately modulated by OKT3 mAb (NK, IH, NT, AS, KT, and EF) were examined, the increases in the percentage of Tac antigen-bearing cells and their MFI caused by OKT3 mAb were evident (Figs 2 and 3). Therefore, these two phenomena, the modulation of T3 antigen and the expression of Tac antigen, are closely related, and T3–Ti complex activation can mediate Tac antigen expression on most ATL cells. This suggests that T3 antigen on ATL cells is already modulated in vivo by unknown agents.

T3 and Tac antigens on cultured neoplastic cells. T3 and Tac antigens were examined using cells cultured with IL 2. ATL cells from three patients (NT, TI, AS), non ATL cells from three patients (NB, MG, ST), and normal T cells from three individuals were studied. MFI of T3 antigen increased continuously in all cells examined until day 7, although the percentage of positive cells did not increase (Fig 5). At day 14, decrease in MFI of T3 antigen was observed in one of the ATL cells examined. Interestingly, the percentage of T3$^+$ cells decreased at day 14 in case TI. Percentage of Tac antigen-bearing cells and its MFI on ATL cells continued to increase and reached maximum at day 14 (Fig 6). A subtle increase of Tac antigen-bearing cells was observed

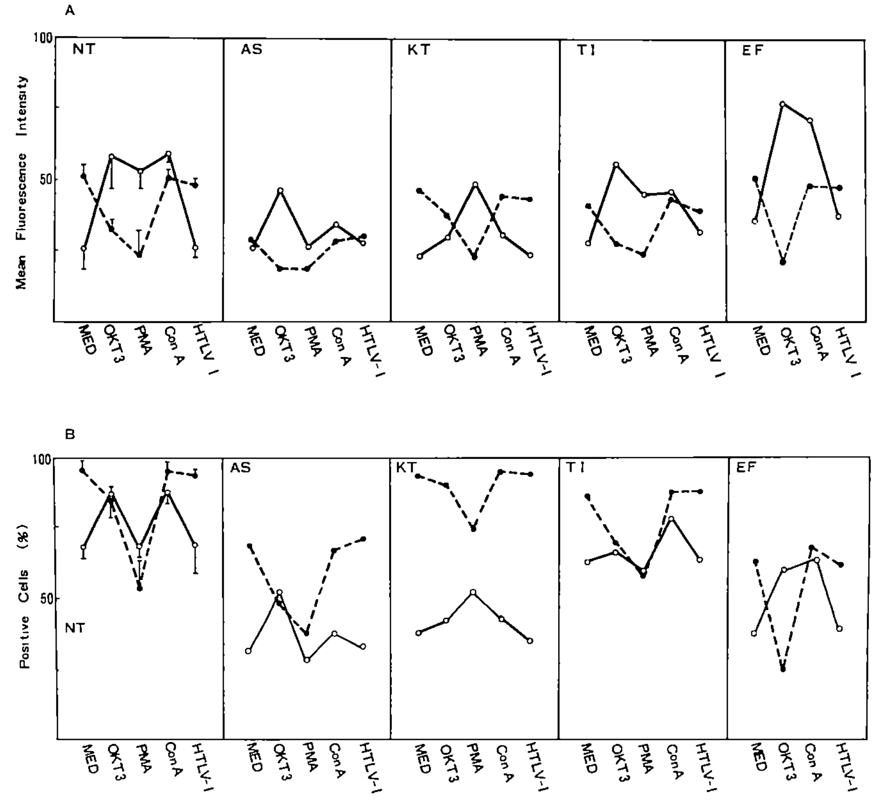

Fig 3. T3 and Tac antigen expression of ATL cells after cultivation with various agents. Mean fluorescence intensity of T3 antigen (A) and percentage of Tac antigen-positive cells (B) of chronic ATL cells.

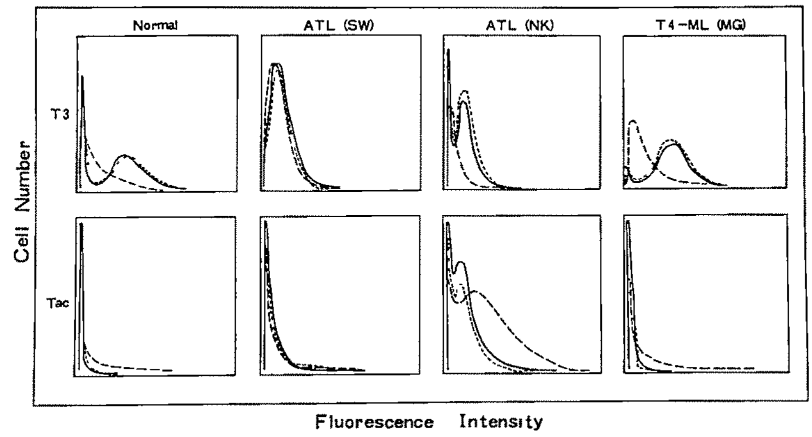

Fig 4. Representitive data of hitogrums of T3 and Tac antigen. Peripheral blood T cells from a healthy person, two ATL patients (SW, NK), and one patient with T4-malignant lymphoma were cultured with medium (—), OKT3 mAb (---), or HTLV particles (· · · ·). After 18-hour cultivation, cells were stained and analyzed as described in Fig 1.

at day 7, when non-ATL cells and normal peripheral blood lymphocytes were used. But the increase was not so marked.

Effect of HTLV-I particles and envelope protein on T3 antigen modulation. It was proposed that leukemogenesis is receptor mediated and that retrovirus interacts with immunospecific or growth receptors of neoplasms.[20,21] So we examined the effects of HTLV-I particles on T3 antigen modulation and Tac antigen expression on all ATL cells. ATL cells were cultured with HTLV-I particles at concentrations of 0.2 to 0.01 U/mL for 18 hours; 0.2 u/mL was chosen as the highest concentration because it saturates HTLV-I receptors on ATL cells as examined by FITC-HTLV particles (unpublished observations, November 1984). At all concentrations, we did not see any significant changes in T3 antigen expression or the expression of Tac antigen on ATL cells from seven cases caused by HTLV-I particles (Figs 2 and 4). We also cultured cells from three patients with ATL (NT, TI, AS) with envelope gene products that have been proven to have antigenicity recognized by serum from ATL patients.[19] The concentrations of envelope protein used were 30, 10, and 3 μg/mL. None of these experiments showed changes of T3 and Tac antigens in any sense. Simultaneously, ATL cells from the same three cases were cultured with 10% patient's serum, which was known to contain antibodies against HTLV-I envelope protein,[18] for seven days to determine whether the serum may prevent the binding of viruses to ATL cells, resulting in the increased expression of T3 antigen. However, the cells cultured with the serum did not change their reactivities to T3 and Tac mAb as compared with medium cultured cells (data not shown).

DISCUSSION

We previously reported that the MFI of T3 antigen on ATL cells is low compared with normal T and T8-CLL cells.[11] Here we have shown that malignant T4 cells from three patients whose sera did not contain anti-ATLA-Ab and whose cells did not have proviral DNA of HTLV-I had the normal density of T3 antigen on their surfaces. T3 antigen on ATL cells was relatively resistant to modulation by OKT3 mAb, although T3 antigen on the non-ATL malignant cells was modulated by OKT3 mAb. In addition, the expression of Tac antigen and the marked increase in Tac antigen-positive cells after culture in complete medium were specific to ATL cells. Non-ATL malignant T4 cells expressed Tac antigen modulation of T3 antigen by mAb or after stimulation by mitogens in 18-hour culture.

The expression of Tac antigen and the low density of T3 antigen on ATL cells suggest that T3–TI on ATL cells may be continuously stimulated by unknown agents in vivo. McGrath et al[20,21] proposed the receptor-mediated leukemogenesis hypothesis because murine leukemia virus (MuLV)-

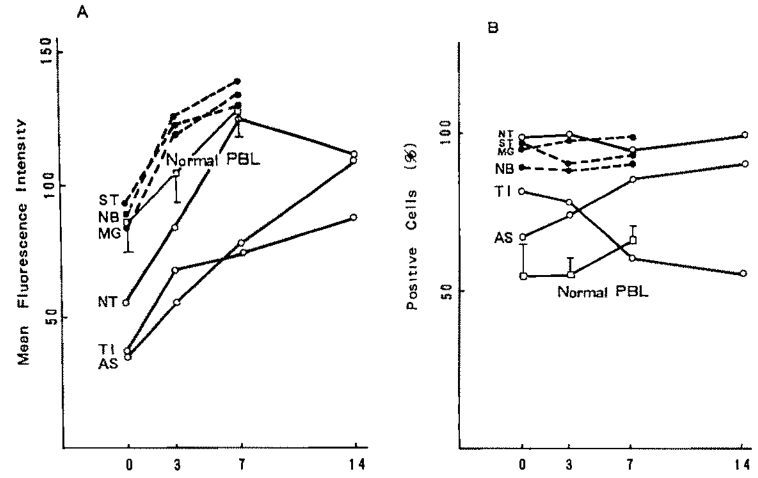

Fig 5. Mean fluorescence intensity of T3 antigen (A) and percentage of T3 antigen-positive cells (B) of cultured cells. (□), mean ± SD of the data of peripheral blood lymphocytes from three healthy individuals; (O), ATL; (●), non-ATL.

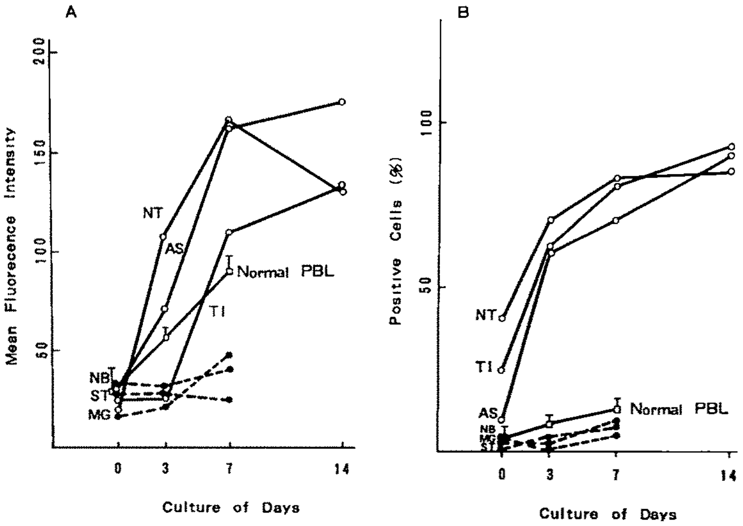

Fig 6. Mean fluorescence intensity of Tac antigen (A) and percentage of Tac antigen-positive cells of cultured cells. Marks used are the same as in Fig 5.

induced thymic lymphoma specifically bound FITC-MuLV, whereas only 0 5% to 2% of normal thymocytes bound them. In this view, the leukemogenic retrovirus express envelope antigens that allow the virus to bind and infect the rare subset of thymic lymphocytes that express receptors complementary to these viral antigens. Thus, it was speculated that slowly transforming retroviruses would interact with immunospecific or growth receptors on the surface of B- and T-cell neoplasms to cause continued rounds of mitogenesis.

Zanders et al[22] reported that the peptides of influenza virus proteins induce the loss of T3 antigen on the surface of cloned T cells specific for influenza virus in 18-hour culture. Therefore, we investigated the effect of HTLV-I particles on the expressions of T3 and Tac antigens on ATL cells to determine whether T3–Ti antigen interacts with HTLV-I protein. The T3 antigen of these cells was not modulated, and there was no enhancement of the expression of Tac antigen on cultivation with HTLV-I particles.

The results indicate that the T3–TI-mediated leukemogenesis hypothesis for ATL cells is less likely. But it is also possible that ATL cells are already tolerant to HTLV-I or other antigens as is suggested by the low density of T3 antigen. Alternatively, envelope protein of HTLV-I may be fragile and cannot react with T3–TI complexes. Thus we used envelope gene products of HTLV-I. Again, no changes in cell surface markers were observed.

It is difficult to interpret the increase of MFI of T3 antigen on cultured ATL cells as well as on non-ATL and normal T cells after cultivation. Increase in MFI of T3 antigen on cultured ATL cells could not be attributed to the selective proliferation of cells that had high density of T3 antigen because it is well known that ATL cells do not proliferate in the presence of IL 2.[23]

There were no differences between acute and chronic ATL cells in our system. However, ATL cells are different from non-ATL T4 malignant cells in MFI of their T3 antigen and in the conditions by which Tac antigen could be induced. Waldmann et al[24] recently reported that ATL cells were Tac positive, whereas most HTLV-negative Sézary cells were Tac negative. Tsudo et al[25] reported that Tac antigen on ATL cells could not be modulated (down-regulation) by anti-Tac mAb, although Tac antigen on Con A-stimulated T cells could be modulated, and proposed that abnormal expression of Tac antigen might play a key role in proliferation of ATL cells. Here we could see increase of MFI or the percentage of Tac antigen-bearing cells by OKT3 mAb as well as PMA, suggesting that Tac antigen on ATL cells were not frozen and could be regulated (up-regulation) by appropriate stimuli. Yodoi et al[26] recently reported a novel lymphokine (ATL-derived factor) that increases the expression of Tac antigen on a human natural killer cell line. A number of other receptors are also related to growth of cells, including transferrin receptor. We have recently observed that transferrin receptors on ATL cells are modulated as those on normal activated T cells (T.U., unpublished observations, August 1984).

Nevertheless, the decrease in MFI of T3 antigen and the expression of Tac antigen were specific to ATL. The expression of Tac antigen on ATL cells was enhanced by T3 mAb stimulation. Thus specific expression of Tac antigen on ATL cells might be the result of the continuous stimulation of T3–TI complexes in vivo by unknown agents.

Relationship of the Clinical Response and Binding of Recombinant Interferon Alpha in Patients With Lymphoproliferative Diseases

By Connie R. Faltynek,* Gerald L. Princler,† Jeffrey L. Rossio,* Francis W. Ruscetti,† Annette E. Maluish,* Paul G. Abrams,‡ and Kenneth A. Foon‡

Patients with hairy cell leukemia (HCL) and chronic lymphocytic leukemia (CLL) were treated with recombinant interferon alpha A (rIFN-αA). The binding of iodinated recombinant interferon-α to baseline samples of peripheral blood mononuclear cells (PBMCs) from the leukemia patients was compared with clinical responsiveness to rIFN-αA. HCL patients (8/10) responded to rIFN-αA therapy, whereas none (0/10) of the CLL patients studied responded. The PBMCs from the eight responsive HCL patients bound approximately twice as much iodinated interferon as the PBMCs from nonresponsive CLL patients. This difference was due to more high-affinity receptors per cell with no difference in the affinity of the interferon-receptor interaction. However, because PBMCs from HCL patients were larger than PBMCs from CLL patients, the cell surface receptor density was similar. The leukemic cells from one of the two nonresponsive HCL patients bound iodinated interferon similarly to the cells from the responsive HCL patients, whereas the leukemic cells from the other nonresponsive HCL patient bound considerably less. The rapidity of response of the HCL patients did not correlate with the level of binding of iodinated interferon. Our results suggest that the absolute number of interferon receptors per cell may be only one of several important parameters in the response to rIFN-αA therapy, and that the responsiveness of a particular lymphoproliferative disease or a particular patient to rIFN-αA therapy cannot be predicted or explained solely by the degree of interaction between IFN and its cell surface receptor.

© 1986 by Grune & Stratton, Inc.

PHASE II TRIALS of natural and recombinant interferon alpha preparations have demonstrated clinical efficacy in a number of lymphoproliferative diseases. The most impressive responses have been reported for patients with hairy cell leukemia (HCL),[1] low- and intermediate-grade non-Hodgkin's lymphoma,[2-4] and cutaneous T cell lymphoma.[5] Although early trials with natural interferon alpha suggested activity for chronic lymphocytic leukemia (CLL) patients,[6] a phase II trial with recombinant interferon alpha A (rIFN-αA) demonstrated no appreciable efficacy in CLL patients.[7]

The initial event in the action of interferon (IFN) is the binding to specific cell surface receptors (reviewed in references 8 and 9). The present study was undertaken to determine whether clinical responsiveness to rIFN-αA therapy can be explained, and therefore predicted, by the degree of binding of IFN to its receptor. In this study, patients with HCL and CLL were treated with rIFN-αA. The binding of iodinated recombinant interferon alpha 2 (^{125}I-rIFNα2) and iodinated recombinant interferon alpha A (^{125}I-rIFN-αA) to pretreatment samples of peripheral blood mononuclear cells was measured. Binding data were compared with clinical responsiveness to rIFN-αA.

MATERIALS AND METHODS

Patients The study group comprised patients undergoing rIFN-αA therapy at the Biological Response Modifiers Program's Clinical Unit at the Frederick (Maryland) Memorial Hospital and consisted of ten cases of HCL[10] and ten cases of CLL.[7] All patients in the study were advised of procedures and attendant risks, in accordance with institutional guidelines, and signed informed consent agreements. With the exception of one nonresponsive patient, only those HCL patients with >70% leukemic cells in their peripheral blood were included in the study. All of the CLL patients had 80% to 100% leukemic cells in their peripheral blood. The patients were diagnosed by examination of bone marrow biopsies. Those with HCL had infiltration of the marrow with mononuclear cells containing filamentous cytoplasmic projections and tartrate-resistant acid phosphatase. Those with CLL had at least 30% mature lymphocytes on a differential count of nucleated marrow cells.

Patients with HCL were treated daily with intramuscular (IM) or subcutaneous injections of rIFN-αA at a dose of 3 × 10^6 units.[10] Responses were defined as a normalization of the peripheral blood cell counts and a >50% reduction in leukemic cells in the bone marrow lasting for at least one month.[10] All of the responding patients are still receiving IFN therapy and have had long-lasting responses, with no relapses witnessed to date. Patients with CLL were treated three times weekly with an IM injection of rIFN-αA at doses ranging from 5 to 50 × 10^6 U/m^2 of body surface area.[7] Responses were defined as a >50% reduction in the size of measurable lesions for at least one month.[7]

Cells Leukemic and normal cells were obtained from peripheral blood by venipuncture. Peripheral blood mononuclear cells (PBMCs) were separated by Ficoll-Hypaque and washed three times with RPMI 1640 medium with 10% fetal calf serum. Cell viability was >95% for all fresh samples. In some cases, frozen cells were used, cell viability was >80%. No difference was observed between the binding of ^{125}I-rIFN-α2 to fresh or cryopreserved cells.

In some experiments, PBMCs were enriched for hairy cells by depletion of contaminant T lymphocytes. PBMCs (0.3 to 1.2 × 10^8 cells) in 1 mL phosphate-buffered saline with 0.1% sodium azide and 2% human serum albumin (Buffer A) were stained with occasional mixing for 30 minutes at 4 °C with 20 μg fluorescein isothiocyanate (FITC)-conjugated monoclonal anti-Leu-4 antibody (Becton Dickinson, Mountain View, Calif). The cells were washed twice with Buffer A and applied to a 7-mL column of Affi-Gel cell-sorting

beads with covalently linked antibodies to FITC (Bio-Rad Laboratories, Richmond, Calif). After incubating for 30 minutes at 4 °C, the unbound cells were eluted in Buffer A. The unbound cells were washed with RPMI with 10% fetal calf serum. For analysis by flow cytometry, the cells were washed and incubated for two hours at 4 °C in RPMI without serum. Flow cytometry was performed as previously described[10] with the following monoclonal antibodies from Becton Dickinson: anti–Leu-4 (pan-T lymphocytes), anti–Leu-12 (B lymphocytes), anti–Leu-11 (natural killer cells), and anti–Leu-M_3 (monocytes).

The B lymphoblastoid Daudi cell line was cultured in Dulbecco's modified Eagle's medium with 10% heat-inactivated horse serum, as previously described.[11] Small resting T lymphocytes were separated from total PBMCs of normal donors by nylon wool depletion of contaminant adherent cells followed by centrifugation through Percoll gradients, as described[12]; fractions 5 and 6, which contained >90% T lymphocytes, were used for these studies.

Interferon. Recombinant IFN-αA was prepared by recombinant DNA technology and purified with monoclonal antibodies by Hoffmann-La Roche, Nutley, NJ, in collaboration with Genentech, San Francisco. Purified rIFN-α2, obtained from Schering-Plough, Bloomfield, NJ, and rIFN-αA were iodinated, as previously described,[13] with an initial specific activity of 10 μCi/μg and 47 μCi/μg, respectively, based on bindable cpm per microgram of protein active in an antiviral assay. Recombinant IFN-αA and rIFN-α2, which are the products of genes cloned by two groups,[14,15] differ only in a single amino acid, lysine *v* arginine, respectively, at position 23, and are considered to be the same IFN subtype. ^{125}I-rIFN-α2, ^{125}I-rIFN-αA, and rIFN-αA were titered, using an assay for reduction of the cytopathic effect of vesicular stomatitis virus on WISH cells, and activity was expressed as units of IFN by comparison with the international standard Ga23-902-530 for IFN-α. Units of biological activity obtained were converted to nanogram IFN, using the specific activity of pure rIFN-αA (2×10^8 U/mg protein).

Binding assays. Binding assays and competitive displacement experiments were performed similarly to those previously described, using cultured cell lines.[13] For standard binding assays in the present experiments, 3×10^6 to 1.1×10^7 cells in 0.5 mL RPMI 1640 medium with 5% fetal calf serum were incubated with 1 ng ^{125}I-rIFN-α2 or 0.3 ng ^{125}I-rIFN-αA for 1.5 hours at 4 °C. In competitive displacement experiments, increasing amounts of unlabeled rIFN-αA were added to standard binding assays. At the end of the incubation, the samples were layered over 0.2 mL of a 2:1 mixture of di-*n*-butylphthalate:dinonylphthalate in microfuge tubes at 4 °C, as previously described,[13] and centrifuged for two minutes at 10,000 g. The supernatant was aspirated, and the microfuge tube tip, which contained the cell pellet, was counted in a gamma counter (Beckman, Fullerton, Calif) with 40% efficiency. A blank reaction, containing no cells, bound less than 50 cpm over the machine background; this blank was subtracted from all bound cpm reported. The binding of ^{125}I-rIFN-α2 in the presence of 133-fold excess of unlabeled rIFN-αA was defined as nonspecific binding and was subtracted from total binding for Scatchard analysis. Nonspecific binding defined in this way constituted 10% to 20% of the total binding.

Cell sizing. Cell volume distributions were measured with a Celloscope (Particle Data, Elmhurst, Ill), which was standardized with 10.25-μm-diameter polymer latex beads. The data were plotted and analyzed by computer to determine the mean cell volume in each cell preparation.

RESULTS

Eight out of ten of the patients with HCL evaluated in the present study responded to rIFN-αA therapy with dramatic improvement in their hematologic parameters, as shown by normalization of the number of erythrocytes, white cells, and platelets.[10] Surface marker studies with monoclonal antibodies demonstrated a significant decline in the TAC-positive, B cell antigen-positive cells after rIFN-αA therapy. In contrast, none of the CLL patients included in this study responded to rIFN-αA.[7]

The binding of ^{125}I-rIFN-α2 was measured to PBMCs from normal donors and to pretreatment samples of PBMCs from nonresponsive CLL patients and from responsive HCL patients having >70% circulating leukemic cells. The mean cpm bound per 10^7 cells in standard binding assays is shown in Table 1. The mean binding of ^{125}I-rIFN-α2 to PBMCs from CLL patients was only slightly higher than the binding to PBMCs from normal donors. However, the mean binding to PBMCs from HCL patients was more than two times higher than the binding to PBMCs from CLL patients (Table 1). The binding of ^{125}I-rIFN-α2 to the lymphoblastoid B cell line Daudi is shown in Table 1 for comparison. This cell line is highly sensitive to the antiproliferative effect of IFN in vitro[16] and expresses high levels of receptors for IFN-α.[11,13]

Because the binding of IFN at 4 °C is a cell surface event,[17] the data can be expressed as cpm bound per equivalent cell surface area. Therefore, cell volume distributions and mean cell volume in the PBMC preparations were measured. Representative sizing profiles of PBMCs from a normal donor, a CLL patient, and a HCL patient are shown in Fig 1. As shown in Table 1, the mean volume of the PBMCs from HCL patients was almost two times greater than the mean volume of the PBMCs from CLL patients and from normal donors. Making the assumption that the cells were perfect spheres, the mean binding per equivalent surface area was 30% lower for PBMCs from patients with CLL than from patients with HCL. However, because hairy cells have many cytoplasmic projections, and thus are not perfect spheres, the surface area of hairy cells is much greater than calculated here. Therefore, the difference in cpm per surface area between CLL and HCL is even less than estimated by this calculation. The mean binding per equivalent surface

Table 1. Binding of ^{125}I-rIFN-α2 to PBMCs From Normal Donors and From HCL and CLL Patients Before Commencing rIFN-αA Therapy

Cells	No of Patients	cpm/10^7 Cells*	Cell Volume (μm^3)	cpm/10^7 μm^2 Surface Area
PBMCs from responsive HCL patients	8	900 ± 163	330	3.90

Daudi cells		4,110	1,216	7.47

The binding of ^{125}I-rIFN-α2 to PBMCs and Daudi cells and the mean cell volume were measured, as described in Materials and Methods. The cell surface area was calculated from the volume, assuming that the cells were perfect spheres.

*Mean cpm bound ± SD

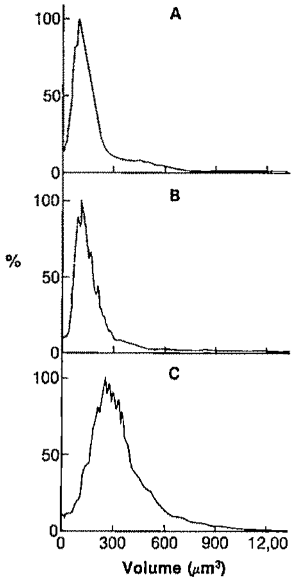

Fig 1. Cell volume analysis of PBMC preparations. Cell volume distributions, determined with a Celloscope, are shown for representative PBMC preparations from a normal donor (A), a patient with CLL (B), and a patient with HCL (C). The number of cells per channel is expressed as a percentage of the maximal signal.

area of PBMCs from normal donors was somewhat lower than the binding to either group of leukemia cells (Table 1).

The higher level of binding of ^{125}I-rIFN-α2 to PBMCs from responsive HCL patients than from nonresponsive CLL patients could be due to either more receptors or a higher affinity of the receptor for the IFN. To assess this, Scatchard plots were constructed from competitive displacement binding curves. In these experiments, a trace amount of ^{125}I-rIFN-α2 was incubated with the cells in the presence of increasing amounts of rIFN-αA. A representative competitive displacement binding curve is shown in Fig 2A. Transformation of these data by the method of Scatchard is shown in Fig 2B. All the Scatchard plots from these experiments, with the exception of that obtained with the Daudi cell line, were curvilinear. As previously discussed,[13,18] many experimental conditions can give rise to artifactual curvilinear Scatchard plots. Therefore, the physiological significance, if any, of these apparent curvilinear Scatchard plots is not presently known.

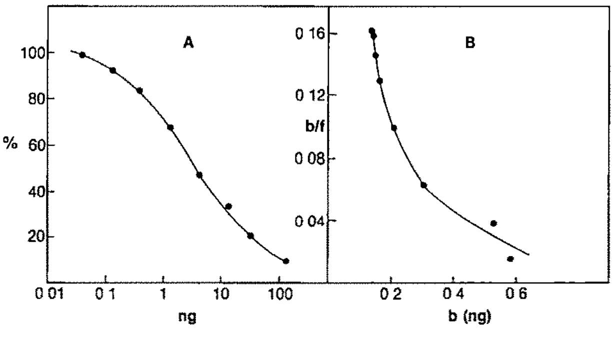

Fig 2. Competitive displacement of ^{125}I-rIFN-α2 by rIFN-αA and Scatchard analysis of the data. PBMCs (1.1 × 10^7 cells) from a patient with HCL were incubated with 1 ng ^{125}I-rIFN-α2 and the indicated amounts of rIFN-αA, as described in Materials and Methods. (A) The binding of labeled IFN is expressed as a percentage of the binding in the absence of unlabeled IFN. (B) The competitive displacement binding data were analyzed by the method of Scatchard with nonspecific binding subtracted, as described in Materials and Methods.

From the high-affinity portion of the curve, the number of receptors per cell and the affinity of the IFN-receptor interaction were estimated. As shown in Table 2, the number of receptors per PBMC from the HCL patients was approximately two times greater than the number of receptors per PBMC from a representative CLL patient. There were fewer receptors on small resting T lymphocytes than on either of the leukemia cell populations. When the number of receptors was expressed per equivalent cell surface area, these differences were substantially reduced. Indeed, as discussed earlier, because of the morphology of the hairy cells, the difference in receptors per surface area is even less than that shown in Table 2. The affinity of the IFN-receptor interaction was the same on all the cells analyzed (Table 2). These results demonstrated that the differences in the binding of ^{125}I-rIFN-α2 to PBMCs from responsive HCL patients compared with those from nonresponsive CLL patients shown in Table 1 could be attributed to differences in the number of receptors per cell with no differences in the affinity of the IFN-receptor interaction.

The data reported thus far compared the binding of ^{125}I-rIFN-α2 to PBMCs from responsive HCL patients with those from nonresponsive CLL patients. However, not all the HCL patients responded to rIFN-αA therapy and the rate of response varied. We compared the responsiveness and the rate of response to therapy with the binding of ^{125}I-rIFN-α2 to PBMCs from HCL patients having >70% circulating leukemic cells. As shown in Table 3, the binding of ^{125}I-rIFN-α2 to PBMCs from these HCL patients ranged from 694 to 1,218 cpm per 10^7 cells, with the exception of patient I, whose cells bound only 207 cpm. After 20 weeks of therapy, HCL patient I did not show any response. The hairy cell count did not decline, which was usually the first sign of response seen within the first week of therapy. In addition, there was no improvement in granulocytes, platelets, or

Table 2. Scatchard Analysis of Competitive Displacement Binding Experiments

In this comparison, a positive response is defined as a >90% decrease in the absolute number of hairy cells in the peripheral blood All of these patients, except patient I, had a normalization of erythrocytes, granulocytes, and platelets within eight to 35 weeks of initiating therapy. The binding of ^{125}I-rIFN-α2 to PBMCs was measured as described in Materials the Methods.

*No reduction in circulating hairy cells or improved blood counts after 20 weeks.

hemoglobin. Interestingly, this patient had massive splenomegaly, which may have contributed to the lack of detectable response. With the other HCL patients there was no correlation between the cpm bound to PBMCs and the length of therapy before a >90% reduction in circulating hairy cells was observed (Table 3).

After this initial study was completed, PBMCs from a second nonresponsive HCL patient were evaluated for IFN-α receptors. However, because only 28% of the circulating PBMCs from this patient were leukemic, it was necessary to enrich for the hairy cells. As described in Materials and Methods, PBMCs were partially depleted of T lymphocytes by cell-sorting affinity chromatography. As shown in Table 4, this procedure reduced the level of Leu-4–positive T lymphocytes and enriched for Leu-12–positive cells; Leu-12, a B cell marker, correlates with the percentage of hairy cells in these patients. This procedure did not appreciably affect the ability of the cells to bind iodinated IFN, as shown for patients A and I. In these experiments, ^{125}I-rIFN-αA rather than ^{125}I-rIFN-α2 was used. Although the absolute number of cpm bound was different, the ratio of binding of ^{125}I-rIFN-αA to PBMCs from patients A and I shown in Table 4 was similar to that previously observed with ^{125}I-rIFN-α2 (Table 3). With both types of iodinated rIFN-α, cells from the nonresponsive patient (I) bound considerably less iodinated rIFN-α than the cells from the responsive patient (A). As shown in Table 4, PBMCs from the other nonresponsive HCL patient (J), when enriched for hairy cells, bound intermediate levels of ^{125}I-rIFN-αA. However, this enriched population of cells was still only 48% Leu-12 positive. Analysis by flow cytometry of unfractionated PBMCs from this patient showed that besides the Leu-4– and Leu-12–positive cells, 12% of the cells were positive for Leu-11, whereas none were positive for Leu-M3, suggesting that there were natural killer cells but no monocytes in the PBMCs of patient J. Therefore, the affinity column-enriched preparation from patient J probably contained large granular lymphocytes (LGLs) in addition to the hairy cells and T lymphocytes. When assayed for the binding of ^{125}I-rIFN-αA under the same conditions as in Table 4, highly enriched preparations of T lymphocytes bound 530 cpm per 10^7 cells and LGLs bound 810 cpm per 10^7 cells. The calculated binding of ^{125}I-rIFN-αA to a cell population consisting of 50% hairy cells (using the cpm bound to affinity column-purified cells from patient A), 25% T lymphocytes, and 25% LGLs was 1,860 cpm per 10^7 cells, which was similar to the binding observed to the hairy cell-enriched preparation from patient J (Table 4). These results suggest that the leukemic cells from nonresponsive patient J bound iodinated IFN at the same high level as the responsive HCL patients, rather than at the low level observed with the other nonresponsive HCL patient I.

Table 4. Binding of ^{125}I-rIFN-αA to PBMCs Enriched for Hairy Cells From Responsive and Nonresponsive HCL Patients

Patient	Response to IFN Therapy	% HC*	Enrichment	Flow Cytometry†		cpm/ 10^7 Cells
				Leu-4	Leu-12

Positive and negative responses are as defined in Materials and Methods. PBMCs were analyzed before (—) and after (+) enrichment for hairy cells by T cell depletion as described in Materials and Methods The binding of ^{125}I-rIFN-αA to the cell populations was measured as described in Materials and Methods. NT, not tested.

*Percentage of PBMCs that are hairy cells as determined by morphology

†Percentage of positive cells.

DISCUSSION

In the work described here, we have examined whether the clinical responsiveness or nonresponsiveness of lymphoproliferative diseases to rIFN-αA therapy can be explained, and therefore predicted, by the level of binding of IFN to its cell surface receptor. Patients with HCL and CLL were studied. Eight out of the ten HCL patients included in the study have responded to rIFN-αA therapy as previously described.[10] Similar responses for HCL patients treated with rIFN-α2 have been reported.[19,20] The patients with CLL showed a poor response.[7]

PBMCs from responsive HCL patients bound more than twice as much ^{125}I-rIFN-α2 as the PBMCs from nonresponsive CLL patients. It should be mentioned that in these studies, PBMCs from HCL patients were more than 70% leukemic, whereas PBMCs from CLL patients were nearly 100% leukemic. The major contaminating cells in the peripheral blood from CLL patients were neutrophils, which were removed by Ficoll-Hypaque treatment. The major contaminating cells in the PBMCs from HCL patients were T lymphocytes and LGLs. Because, as discussed in Results, these contaminating cells bound considerably less iodinated IFN-α than did hairy cells, their presence resulted in an underestimation of the binding to hairy cells, making the differences in binding between pure populations of HCL and CLL even greater than shown in Table 1. The more than twofold difference between the binding of iodinated IFN-α to PBMCs from HCL and CLL patients was attributable to more high-affinity receptors per cell with no difference in the affinity of the IFN-receptor interaction. However, we found that the cell volume of the PBMCs from HCL patients was approximately twice that of the PBMCs from CLL patients. Moreover, the hairy leukemia cells had many cytoplasmic projections, which further increased their cell surface area. Therefore, our results indicate that the PBMCs from HCL patients have a greater absolute number of high-affinity IFN-α receptors per cell than do PBMCs from CLL patients, but that they have a similar cell surface high-affinity IFN-α receptor density due to differences in cell size and morphology.

We asked whether the twofold difference between HCL and CLL patients in the absolute number of high-affinity IFN-α receptors per PBMC could account for the responsiveness of the HCL patients and nonresponsiveness of the CLL patients to rIFN-αA therapy. It is possible that if a threshold number of interactions between IFN and its receptor is required for an antiproliferative response, the absolute number of receptors per cell, rather than receptor density, is an important parameter in determining a response. Although in vitro antiproliferative responsiveness may not necessarily correlate with clinical responses, the available data on the Daudi cell line is consistent with the above hypothesis, since these cells express a high number of IFN-α receptors[11,13] and are sensitive to the antiproliferative effects of this IFN.[16] Moreover, in some cases, a reduced responsiveness or lack of response to the antiproliferative effects of IFN has been correlated with a low level of IFN receptors.[21,22] With other cell lines there is no direct relationship between the number of receptors per cell and the responsiveness to IFN.[23,24]

Although the data with HCL and CLL patients suggested that the absolute number of IFN receptors per cell may be an important parameter, the following observations provided evidence that this is not a sufficient criterion to explain or predict a clinical response or the rapidity of response to rIFN-αA therapy. First, among the responding HCL patients, there was no correlation between the level of ^{125}I-rIFNα2 binding and the rapidity of response to rIFN-αA therapy. Second, an enriched preparation of hairy leukemic cells from one of the two nonresponsive HCL patients, when normalized for percentage of leukemic cells, bound iodinated IFN-α similarly to the leukemic cells from the responsive patients. This patient was removed from study after eight weeks due to progressive disease. Although the leukemic cells from the other nonresponsive HCL patient bound the lowest amount of iodinated IFN-α, it is premature to conclude that the lack of response is due solely to the low IFN binding; however, it may be a contributing factor. This patient showed no improvement after rIFN-αA therapy and was removed from study because of increasing pain from splenic infarcts. Interestingly, both of the nonresponding patients had massive splenomegaly. One hypothesis is that the tumor-infiltrated spleens prevented IFN from saturating receptors. Although higher doses of rIFN-αA might have been effective, we felt that they might have led to unacceptable toxicity and instead elected to treat these two patients with 2-deoxycoformycin. Both patients initially responded to deoxycoformycin therapy with improved blood counts and significant reduction in the size of their spleens. Taken together, the data presented here indicate that the responsiveness of a particular patient to rIFNαA therapy cannot be predicted or explained solely by the degree of interaction between IFN and its cell surface receptor.

At the present time, the molecular mechanism for the antiproliferative state induced by IFN is poorly understood. Using cultured cell lines, it has been shown that after the binding of IFN to its receptor, the IFN–receptor complex is internalized by the cells,[13,17,25,26] resulting in down-regulation or reduced number of IFN receptors at the cell surface.[27] Whether internalization of IFN or its receptor is required for the biological responses to IFN has not been resolved.[13,17,28,29] After several hours, new proteins induced by IFN treatment can be detected in the cells.[30] Two of these proteins, 2′5′ oligo(A) synthetase and a protein kinase, are important in the IFN-induced antiviral state.[31] Whether either of these proteins also plays a role in the antiproliferative response to IFN has not been established.[32] Likewise, the function of the other induced proteins is not known.

Because the molecular mechanism for the IFN-induced antiproliferative state in vitro is so poorly understood, it is difficult to explain why some malignancies have responded well to IFN therapy in vivo and why others have not. It may relate to the fact that some malignancies have a viral etiology, and thus the antiviral action of IFN could play a role. In this regard, a T cell variant of HCL was found to contain HTLV-II,[33] a human retrovirus associated with disease. It is also possible that the responsiveness of a particular malignancy or a particular patient to IFN therapy may lie not only with an effect of IFN on the malignant cells, but also with an effect of IFN on the immune system. Further research is required to elucidate molecular mechanisms of the antiproliferative action of IFN in vitro and in vivo.

ACKNOWLEDGMENT

We thank Judy Beacht for preparation of the manuscript, Paul Miller and Dr Henry C. Stevenson for assistance with the Celloscope, Erskine Johnson for performing the IFN titrations, Helen Rager and Robin Rice for performing the cell-sorting affinity chromatography, Roy Overton for the analysis by flow cytometry, Dr Corrado Baglioni and Susan J Littman for the ^{125}I-rIFN-α2 used in these studies, and Dr John Ortaldo and Hilda Porter for the purified T lymphocytes.

On the Mechanism of Hb F Elevations in the Baboon by Erythropoietic Stress and Pharmacologic Manipulation

By D. Lavelle, J. DeSimone, P. Heller, D. Zwiers, and L. Hall

Maximal fetal hemoglobin (Hb F) elevations in the baboon subsequent to phenyl hydrazine-induced hemolytic anemia, bleeding, bleeding plus hydroxyurea (HU), or cytosine arabinoside were two to three times lower than those achieved with bleeding plus 5-azacytidine (azaC). Because, in the baboon, maximal elevations in F cell numbers occurred with bleeding alone, changes in the levels of Hb F in hemolysates and in Hb F per F cell could be considered to be due to the administered drugs. Erythropoietic toxicity of azaC was minimal, making it unlikely that the marked elevations of Hb F were due to shifts in the population of erythroid progenitors and precursors and more likely that they were related to a biochemical effect of the drug on DNA. The data indicate marked DNA hypomethylation. This was also found to be associated, but to a much lesser extent, with the modest Hb F elevations after bleeding, hemolysis, and treatment with HU. This drug had greater erythroid toxicity than azaC, and it appeared that the Hb F elevations occurred mainly on the rebound from the early cytotoxicity. The explanation of the molecular DNA changes with this drug and in erythropoietic stress alone remains unknown.

FETAL HEMOGLOBIN (Hb F) LEVELS in baboons increase in response to erythropoietic stress due to bleeding[1,2] and are further augmented by the administration of 5-azacytidine (azaC).[3,4] Before its use in baboons, azaC had been found to enhance gene expression in vitro in several eukaryotic cell systems,[5,6] presumably because of its inhibiting effect on the enzymatic methylation of DNA. Later studies showed that hydroxyurea (HU)[7] and cytosine arabinoside (araC),[8] cytotoxic agents active in the S-phase, and vinblastine, which inhibits mitosis,[9] also increase Hb F levels in primates, although not as markedly as azaC. This suggests that a perturbance of the erythroid progenitor pool contributes to the production of erythrocytes containing various amounts of Hb F (F cells). Our studies[3] on the effect of azaC in baboons, kept anemic by bleeding, indicated that the increase in Hb F occurred in two phases: (1) accelerated erythropoiesis due to erythropoietic stress leads to maximal elevations in the number of F cells up to a genetically determined limit[2] and (2) azaC further increases the concentration of Hb F per F cell without further increase in the number of F cells.[3] The former is explainable by present concepts of the relationship of premature maturation of erythroid progenitor cells and F cell production[10]; the latter seemed best explained by a direct biochemical effect of the drug on γ-gene expression, possibly by way of DNA hypomethylation.[3] Because, in baboons, the maximal number of F cells was observed after bleeding alone, before the use of drugs,[3] an opportunity was offered to compare the effects of azaC, HU, and araC on Hb F levels beyond those attained by bleeding alone. In addition, we attempted to determine whether in the baboon the degree of γ-gene–specific and of genomic hypomethylation in erythroid precursor cells could be correlated with the increased Hb F levels.

MATERIALS AND METHODS

Experimental animals and mode of treatment. The effect of azaC on Hb F production was compared with that of HU or araC in 14 baboons kept anemic by bleeding. In six of these 14 animals, hemolytic anemia was induced by phenylhydrazine (PHZ) to compare the effect of a more severe erythropoietic stress than bleeding with the Hb F production due to the drugs. Eleven additional anemic (by bleeding) animals received only azaC and two only HU, for a total of 27 animals. Bone marrow aspirations were performed for examination of the morphological features and for DNA extraction in almost all animals before and after treatment. Of the 27 baboons, 18 belonged to the species *Papio anubis* and nine to that of *P cynocephalus*. The importance of this distinction lies in the fact that most baboons who respond to erythropoietic stress and azaC with the production of high levels of Hb F belong to the species *P anubis*, and most low Hb F responders belong to the species *P cynocephalus* [11] The age of most animals was two to six years; four were older (2057, 2883, 3200, and 3433) and three, younger (5004, 5005, and 5058).

All animals were bled before drug treatment to reduce the packed red cell volume (PCV) to approximately 20% within five days Variable amounts of blood calculated to maintain the PCV at this level were withdrawn almost daily throughout the experimental period. The first dose of the drug was given not earlier than 12 days after the start of phlebotomies. Of the 14 individual animals in which the effects of different drugs and of PHZ hemolysis on Hb F production were compared, all received 5-azaC; eight also received HU and four, araC. Each treatment started only after complete recovery from the previous one and when all measured hematologic parameters were normal. In the majority of animals, the dosage of azaC was 4 mg/kg/d administered intravenously 5 days a week for two to three weeks. By that time, maximal Hb F levels were reached. Ten of the 25 animals received only 0.5 mg/kg/d together with tetrahydrouridine (THU), 10 mg/kg/d. This agent prevents the rapid inactivation of azaC to 5-azauridine by inhibiting cytidine deaminase and has previously[12] been shown to make the reduction of the dose of azaC possible without interfering with the maximal effect on Hb F production. The dosage of HU was 100 mg/kg/d for an average of 1.5 weeks in eight animals; one (3433) received 25 mg and one (4625), 50 mg. AraC was given at a dose of 4 mg/kg/d for one to four weeks. The duration of treatment with these two drugs was determined by signs of worsening erythropoietic toxicity PHZ was administered intraperitoneally at a dose of 20 mg/kg/d for five days without prior bleeding of the animals.

Peripheral blood. Complete blood counts, white cell differential, and reticulocyte counts were performed daily throughout the period of observation. Hb F levels were determined daily by alkali denaturation[13] and in some of the hemolysates by high-performance liquid chromatography (HPLC), using a large-pore (300 Å) C_4 reverse phase resin.[14] There was no significant difference in the results of the two methods.

Bone marrow. Bone marrow samples were obtained from both untreated and treated animals after two weeks of bleeding and two to three days after the end of drug treatment. These bone marrows were examined morphologically, and DNA was extracted from the original aspirate in the case of marked (80% to 90%) erythroid hyperplasia or from separated cells Separation of erythroid from nonerythroid cells from normal bone marrow was partially accomplished by Ficoll-Hypaque density-gradient centrifugation and unit-gravity sedimentation.[15] Granulocytes were separated from normal peripheral blood by Ficoll-Hypaque centrifugation.

DNA. DNA was purified from bone marrow cells and from granulocytes of peripheral blood by phenol extraction and proteinase K digestion.[16] The deoxymethylcytosine (dmC) content of the DNA was determined by HPLC on a 4.6 × 250-mm C18 reverse phase column (Altex Ultrasphere) at 35 °C according to described techniques[17] with minor modifications. Isocratic development with 0.02 mol/L KH_2PO_4, 8 5% methanol, pH 7, for eight minutes was followed by a gradient in methanol to 30% in ten minutes. The flow rate was 1 mL/min. The results were expressed as percentage of total deoxycytosine.

For Southern blotting,[18] 10 μg of DNA were digested with a threefold to fourfold excess of the appropriate restriction enzyme overnight at 37 °C. The DNA digestion was monitored by the addition of 0.3 μg of lambda DNA to an aliquot of the digestion mixture. Digested DNA samples were fractionated on 0.8% agarose gels, transferred to nitrocellulose membranes,[18] and hybridized to a nick translated 2.1-kb *Bgl*II-*Bam*HI fragment subcloned in PBR 322, containing the 5′ portion of the human $^{G}\gamma$ gene. Hybridizations were conducted as described by Wahl et al.[19] The membranes were washed three times for 15 minutes each with 2 × standard saline citrate (SSC) and 0.1% sodium dodecyl sulfate (SDS), at room temperature, followed by a final stringent wash with 0.5 × SSC and 0 1% SDS, at 65 °C Autoradiography of the membranes was performed for two to four days at −80 °C, using intensifying screens.

RESULTS

Hb F levels. Table 1 shows the maximal values of Hb F in the 14 animals that received, sequentially, azaC and HU or araC. Six were also tested for the effect of PHZ-induced hemolytic anemia on Hb F levels. The highest maximal levels were achieved with azaC. As described previously,[3] the level of Hb F started to increase rapidly after the start of treatment with azaC, and the maximum was usually obtained after the second five-day period (Fig 1C). The maximal Hb F level appeared to be influenced mainly by genetic factors, which determine the difference between high (mostly *P anubis*) and low (mostly *P cynocephalus*) Hb F responders. This difference was also noted with the other treatments. Although age, as seen in animal 3433, which was 8 years old, diminishes the magnitude of the Hb F response to erythropoietic stress, azaC overcomes this restricting influence of age and increases the Hb F level to the genetically determined limit.

The Hb F values in all 25 animals that received azaC are listed in Table 2. The average value in the 17 high Hb F responders was 55.9%; in the low responders it was 33.7%. A few values in the 30% to 40% range overlapped. The distinction between the high and low Hb F response was less sharp after bleeding alone (Table 1) because the animals were of different ages.[2]

In the eight animals that received 100 mg/kg/d HU, the Hb F response was two to three times lower than with azaC (Tables 1 and 3) and the duration of treatment was limited by hematologic toxicity. Typical Hb F responses, as shown in Figs 1A and B, appeared to occur in all instances, with the recovery from this toxicity when the reticulocyte count rose and the bone marrow showed erythroid hyperplasia. The same impression was obtained from the effects of araC, but because of the relatively low levels of Hb F and the predictable toxicity, this drug was used in only four animals. The levels of Hb F after PHZ-induced hemolytic anemia were similar to those achieved by HU; in two animals they were higher.

*A, *P anubis;* C, *P cynocephalus.*

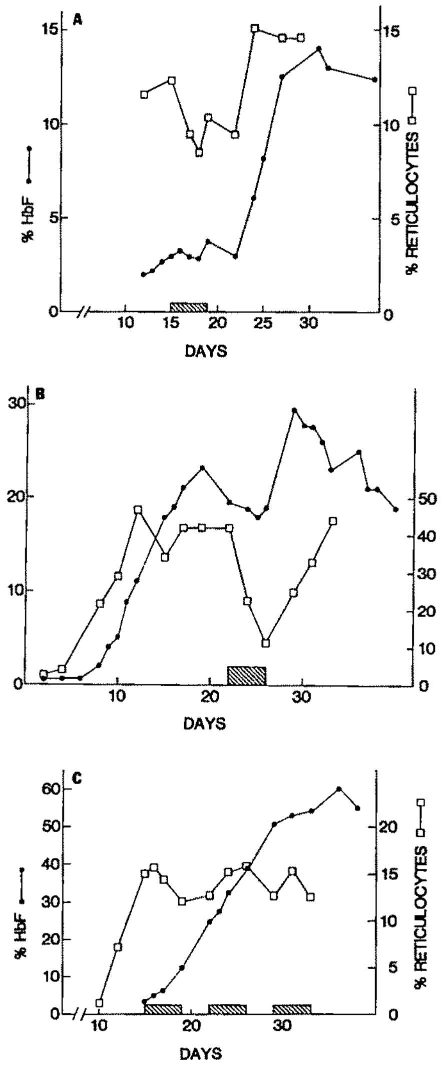

Fig 1. Changes in reticulocyte percentages and Hb F levels of bled baboons after treatment with HU or azaC. (A) Adult animal 8 years old (#2843) treated with HU. (B) One-year-old animal (#5005) treated with HU. (C) Three-year-old animal (#4615) treated with azaC. All animals had PCVs of 20% to 22% maintained by bleeding.

Hematologic toxicity. Tables 2 and 3 show the effect of azaC and HU on reticulocytes and white blood cells. Platelet counts were hardly affected and are not listed. Although all drugs in the administered dosages produced a decrease in the white blood cell count, with seemingly greater influence on granulocytes than on lymphocytes, there were marked differences in their effects on red cell production. AzaC (4 mg/kg/d) changed erythropoiesis very little, as shown by persistent erythroid hyperplasia of the bone marrow and the relatively small fluctuations of the reticulocyte counts, with an average reduction of 8% (Table 2 and Fig 1), whereas HU and araC in the administered dosage decreased the cellularity of the bone marrow and reduced the average reticulocyte percentage by 53% and 36%, respectively. Typical relationships in the time sequence of the reticulocyte count and the Hb F elevations in animals treated with azaC or HU are shown in Fig 1. In the azaC-treated animals, the reticulocyte elevations due to bleeding continued throughout the sequential five-day courses of azaC. In the animals treated with HU, the elevations of the reticulocyte count due to the preceding period of bleeding decreased after the start of treatment and the Hb F level increased only with the return of the reticulocytosis. These consistent differences in the effects of azaC and HU suggest different mechanisms of drug action.

Effect of treatment on γ-gene and genomic methylation. The level of specific methylation in the region of the ${}^{I}\gamma$-gene (analogous to human ${}^{G}\gamma$)[11] was measured by Southern blot analysis of bone marrow DNA samples digested with the methylation-sensitive enzyme *Hpa*II or its isoschizomer, *Msp*I. In a restriction enzyme cleavage map of the baboon ${}^{I}\gamma$-gene (Fig 2), a *Hpa*II site exists immediately 5′ to the coding region of the gene and another such site is located within the large second intervening sequence. In Southern blots of *Bgl*II-*Hpa*II or *Bgl*II-*Msp*I, doubly digested DNA samples hybridized to the 2.1-kb *Bgl*II-*Bam*HI human ${}^{G}\gamma$-probe. Hybridization to a 1.5-kb band was observed, provided that the site immediately 5′ to the coding sequence was hypomethylated. Hybridization occurred to a 0.8-kb band if both *Hpa*II sites were hypomethylated. Because a single *Hpa*II site is involved in the generation of the 1.5-kb fragment, changes in the intensity of this band in Southern blots provide a sensitive means for determining the degree of methylation at this locus. Digestion with *Bgl*II alone resulted in hybridization to a 14.5-kb band.

The extent of γ-gene methylation observed in bone marrow DNA samples obtained from animals undergoing various drug treatments is shown in Fig 3. The 1.5-kb band was found to be visibly more intense in bone marrow DNA samples obtained from animals treated with HU (lane 1), PHZ (lane 3), or bleeding alone (lane 7) than in DNA samples from normal bone marrow (lane 5). The 0.8-kb band was also more intense in bone marrow DNA digests from bled and PHZ-treated animals. Thus these various treatments that resulted in increased Hb F levels were also associated with hypomethylation of *Hpa*II sites surrounding the ${}^{I}\gamma$-gene. The same animal (5004) was the source of DNA samples before (lane 5) and after (lane 3) treatment with PHZ. The most striking increase in intensity of the 1.5- and 0.8-kb bands was observed in bone marrow DNA from animals treated with azaC (lane 9). Thus treatment with azaC, which produced the largest increase in Hb F, also resulted in extensive DNA hypomethylation.

Different patterns of hybridization were found in the blots of *Bgl*II–*Msp*I digests of DNA from bone marrow of HU, PHZ, unbled and bled animals (Fig 3, lanes 2, 4, 6, and 8) compared with DNA from azaC-treated animals (Fig 3, lane 10). The 1.5-kb band was the major band observed after azaC treatment, whereas the others showed only a minor band at 1.5 kb. In these samples, a major band was present at 2.3 kb. Failure to observe a major 1.5-kb band in *Bgl*II–*Msp*I digests except when the DNA has been extensively hypomethylated by azaC was probably due to the inability of

*Msp*I to digest the methylated CCGG sequence immediately 5′ to the $^{I}\gamma$-gene. Blockage of this analogous sequence to *Msp*I digestion by methylation has been reported in humans,[20] and results from the inability of *Msp*I to cleave a GGCCGG sequence when the 3′C in this nucleotide sequence is methylated.[21,22]

Normal bone marrow samples were found to contain approximately 30% erythroid cells, whereas those obtained after bleeding, HU, and PHZ were 80% to 90% erythroid. Therefore, the increased intensity of the 1.5-kb band observed after bleeding, HU after bleeding, and hemolysis by PHZ could be due merely to an increased proportion of erythroid cells in bone marrow aspirates of erythropoietically stressed animals. To test for this possibility, we compared on the same Southern blot the intensities of the 1.5-kb *Bgl*II–*Hpa*II band from the digest of 30 μg of normal bone marrow

DNA and 10 µg of bone marrow DNA from the same animal after PHZ treatment (Fig 4). The 1.5-kb band of the PHZ sample (lane 4) was at least four to five times as intense as the band observed from normal bone marrow DNA (lane 2), even though only a third of the amount of DNA was loaded into the gel. Thus the observed hypomethylation cannot be explained by a mere enrichment of erythroid cells in the bone marrow samples.

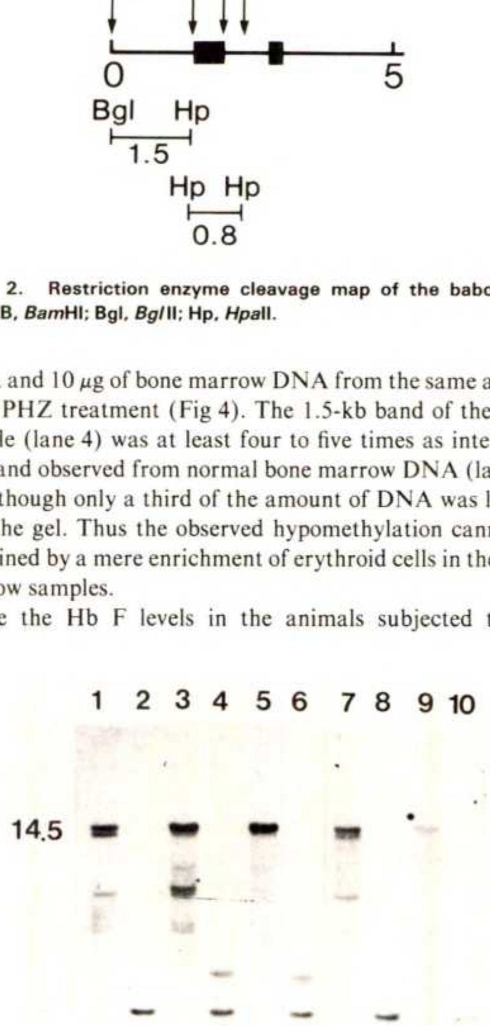

Fig 3. Southern blot analysis of bone marrow DNA restriction enzyme digests hybridized to a human γ-probe (odd numbers: *Bgl*II–*Hpa*II; even numbers: *Bgl*II–*Msp*I): Lanes 1 and 2, Baboon #4778: HU (after bleeding); lanes 3 and 4, #5004: PHZ-induced hemolysis; lanes 5 and 6, same animal: normal; lanes 7 and 8, #5005: bleeding alone; lanes 9 and 10, #4446: azaC (after bleeding).

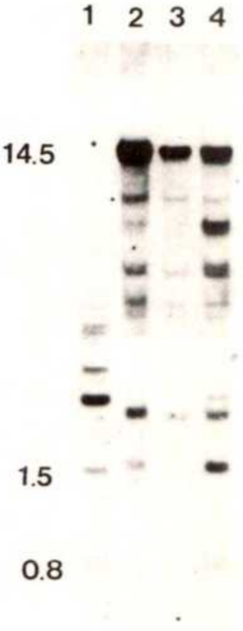

Fig 4. Southern blot analysis of bone marrow DNA (animal #5004) restriction enzyme digests hybridized to a human γ-probe. Lane 1, 10 µg DNA from normal bone marrow digested with *Bgl*II–*MSP*I; lane 2, 30 µg of same DNA digested with *Bgl*II–*Hpa*II; lane 3, 10 µg of same DNA digested with *Bgl*II–*Hpa*II; lane 4, 10 µg of DNA digested with *Bgl*II–*Hpa*II (PHZ-induced hemolysis).

Are the Hb F levels in the animals subjected to the described various treatments proportional to the estimated degrees of DNA hypomethylation? The observations in two animals suggest that this is not the case: Bleeding plus HU treatment of animal 4778 resulted in a maximal Hb F level of 10%, whereas bleeding alone of animal 5005 led to a maximal Hb F level of 23.1% (Table 1). The degree of DNA hypomethylation by Southern blot analysis seemed equal in the two samples (Fig 3, lanes 1 and 7). Thus, in these two animals, the bone marrow DNA was hypomethylated to a similar degree, while the levels of Hb F differed by a factor of 2.3.

We estimated the degree of genomic DNA methylation by determining the percentage of methyldeoxycytosine of total deoxycytosine in the DNA (subsequently designated as dmC content) extracted from bone marrow cells of untreated and treated animals (Table 4). DNA extracted from normal bone marrow, which is approximately 30% erythroid, contained 3.49% ± 0.001% dmC, and DNA from separated bone marrow myeloid cells and peripheral granulocytes contained 3.08% ± 0.007% and 3.01% ± 0.001%, respectively. Thus erythroid cells from normal bone marrow were estimated to contain 4% to 5% dmC. The dmC values of the DNA from erythroid precursor cells of bone marrows with erythroid hyperplasia (80% erythroid), which were obtained from animals after repeated phlebotomies, PHZ, or phlebotomies plus HU were equal at 3% (Table 4) indicating that these treatments were associated with genomic DNA hypomethylation. After azaC, the dmC content was 1.72% ± 0.007%. Thus the lowest levels of genomic DNA methylation were associated with the highest levels of Hb F.

Table 4. Methylcytosine Content of Bone Marrow and Peripheral Blood Cells

	% dmC
Normal bone marrow (N:5)	3.49 ± 0.002
Normal bone marrow myeloid cells (N:3)	3.08 ± 0.007
Normal peripheral blood granulocytes* (N:3)	3.01 ± 0.031
Bone marrow after phlebotomy (N:7)	3.01 ± 0.007
Bone marrow after PHZ (N:4)	3.00 ± 0.001
Bone marrow after HU (N:3)	3.00 ± 0.011
Bone marrow after azaC (N:8)	1.72 ± 0.007

*Granulocytes from peripheral blood and myeloid cells from bone marrow were purified by Ficoll-Hypaque centrifugation and unit-gravity sedimentation.[15] Peripheral blood granulocytes were greater than 90% pure and bone marrow myeloid cells were 75% to 85% pure. Bone marrow of treated animals were at least 80% erythroid. Bone marrow samples were obtained two weeks after the start of daily phlebotomies, one week after start of PHZ injections, two weeks after start of HU and azaC.

DISCUSSION

The data derived from the described experiments in baboons indicate that azaC produces the highest Hb F levels among all experimental manipulations intended to increase these levels, and the highest degree of γ-gene-specific and genomic hypomethylation. The rise in Hb F beginning rapidly after the administration of the drug and the unique magnitude of the Hb F elevations speak for a direct effect of the drug on γ-gene expression in dividing erythropoietic progenitors and precursor cells, including pronormoblasts and normoblasts. Although it is tempting to speculate that DNA hypomethylation precedes the activation of the γ-genes, the exact timing of the two events cannot be determined in such in vivo experiments, as described here.

Recently, Humphries et al[23] also came to the conclusion that azaC has a direct effect on erythropoietic cells on the basis of in vitro and in vivo studies. The authors noted γ-gene hypomethylation in vivo, but because of the Hb F elevations occurring also with HU and araC, they did not attribute any causative significance to this phenomenon. Recent observations of Busslinger et al[24] seem to support the role of hypomethylation in γ-gene expression. These investigators found in in vitro experiments involving the transfer of human γ-gene fragments that methylation of the 5′ end of the human γ-globin gene inhibits the expression of this gene.

According to present concepts,[10] rapid maturation of erythroid progenitor cells, as it occurs in accelerated erythropoiesis, is associated with activation of the Hb F program in these erythroid progenitors, leading to the generation of F cells. Such a mechanism may certainly be set in motion by cytotoxic agents,[25,26] but the remarkably small fluctuations of the elevated reticulocyte count with an average decrease of 8% after treatment with azaC indicate only minor erythropoietic toxicity of this drug at the dosage that leads to the singularly high levels of Hb F. On the other hand, the Hb F elevations that have been found after the administration of HU in patients with sickle cell anemia[27] and in *Macaca fascicularis*[7] and that are not as high as after azaC can be explained by this mechanism. In our experiments with baboons, the Hb F elevations after HU have generally not been higher than in erythropoietic stress, especially if the latter was produced by PHZ hemolysis. These observations suggest that the Hb F elevations after HU depend mainly on the recovery of erythropoiesis after subsidence of the drug's cytotoxic effect. This mechanism seems to apply also to araC[8,28] and vinblastine,[9] which inhibits spindle fiber formation. Although HU is the prototype of a cytotoxic drug, its effect is more complex than is generally assumed, eg, gene amplification by HU has been demonstrated in other cells.[29] It is conceivable that the early appearance of F cells that has been observed 24 to 72 hours after the administration of the drug to patients with sickle cell anemia[27] is due to a transient stimulating effect of the drug on erythropoiesis, but it appears that the change in cell populations during recovery from cytotoxicity is mainly responsible for this phenomenon.

The molecular connection between erythropoietic stress due to bleeding or hemolysis and DNA hypomethylation remains a puzzle. It is conceivable that cellular hyperproliferation produces a similar phenomenon, as has been postulated for the hypomethylation of *Escherichia coli* DNA during amplification in the presence of chloramphenicol,[30] namely, an imbalance between the rate of replication of hyperproliferating cells and the rate of methylation, which are normally closely coordinated. This coordination may be disturbed because the rapid replication leads to a relative deficiency of the rate-limiting DNA methylase. Alternatively, it might be postulated that erythropoietic stress may lead to the amplification of a normally undermethylated erythroid cell subpopulation.

The results of the present study confirm not only the previously described distinction[1] between high and low Hb F responders among baboons, but also the association of these distinctive characteristics with the species *P anubis* and *P cynocephalus*, respectively. This difference is best demonstrable by the Hb F response to azaC. The molecular basis of this difference is not known, but it is independent of the DNA hypomethylating effect of the drug, which was equal in both species.

The favorable influence of Hb F on sickling, provided Hb F and S are in the same cell, and the possibility of increasing Hb F production in β-thalassemia have stimulated the experimental use of azaC and HU in patients with these diseases with favorable results, but their clinical use remains limited because of toxicity and potential carcinogenicity.[25,26,31,32]

Radiobiological Properties of the Human Hematopoietic Microenvironment: Contrasting Sensitivities of Proliferative Capacity and Hematopoietic Function to In Vitro Irradiation

By Joseph Laver, Wolfram Ebell, and Hugo Castro-Malaspina

We describe the effects of in vitro irradiation on the proliferative capacity and hematopoietic supportive function of human marrow stromal cells. To assess the effects on the proliferative capacity of stromal progenitors and differentiated fibroblasts, marrow cell suspensions and trypsin-dispersed marrow fibroblasts were treated with a single dose of gamma radiation at 100 rad/min. Fibroblastic progenitors (CFU-F) showed an exponential decrease in colony formation with increasing doses of irradiation, with a Do slightly higher than that of granulomonopoietic progenitors (CFU-GM); Do values for CFU-F and CFU-GM were 130 and 115, respectively. However, although the CFU-F survival curve exhibited a shoulder (n = 1.3), the CFU-GM curve did not (n = 1.0), indicating that only fibroblastic progenitors have the potential to repair irradiation-induced damage. Passaged marrow fibroblast colony-forming cells also showed a shouldered exponential survival curve with a Do of 110 and n value of 1.4. Marrow stromal progenitors giving rise to adherent layers in long-term marrow cultures also demonstrated a highly radiosensitive proliferative capacity. Stromal layers derived from irradiated marrow suspensions failed to establish adherent layers after relatively low doses of irradiation (over 240 rad) in a dose–response manner. To assess any functional damage in stromal progenitors surviving irradiation, stromal layers derived from marrow suspensions irradiated up to 240 rad were cocultured with freshly isolated autologous hematopoietic cells and assayed for their capacity to support prolonged CFU-GM production. Confluent stromal layers derived from irradiated marrow suspensions sustained CFU-GM production as well as controls. To study the effects of irradiation on the hematopoietic supportive capacity of established marrow-derived stromal layers, 4 to 6-week-old adherent layers were irradiated as described and cocultured with autologous marrow cells enriched for colony-forming cells. Stromal layers irradiated up to 1,320 rad sustained prolonged CFU-GM production, indicating that the hematopoietic supportive function remained intact at this dose of irradiation. In conclusion, we demonstrated that the proliferative capacity of human marrow stromal progenitors, as well as that of their differentiated descendants, is quite sensitive to in vitro radiation, while the hematopoietic supportive function of differentiated stromal cells is relatively resistant to the effects of radiation.

© *1986 by Grune & Stratton, Inc.*

THE EFFECTS OF RADIATION on human hematopoietic cells have been extensively studied in the past. For instance, in vitro irradiation experiments have shown that hematopoietic progenitors have a quite radiosensitive proliferative capacity, with Do values (the dose required to reduce survival to 37%) ranging from 90 to 130 rad[1–5] and little or no capacity to repair radiation-induced sublethal damage (no shoulder on survival curves). Similar studies have demonstrated that, with the exception of lymphoid cells,[6–10] most mature nondividing hemic cells are relatively radioresistant in regard to cell viability and some cell functions.[11–13] Analysis of hematopoietic repopulation in patients treated with local irradiation has confirmed in vivo the high radiosensitivity of hematopoietic progenitors and suggested that the failure of hematopoietic reconstitution occurring after local irradiation with doses over 4,000 rad may be related to irreversible damage of the hematopoietic microenvironment.[14–18]

There is overwhelming evidence documenting the essential role of the marrow microenvironment in the process of hematopoietic engraftment and blood cell formation.[19] The fact that intravenously infused hematopoietic cells repopulate the marrow and not other organs of lethally irradiated recipients indicates that this tissue possesses a special microenvironment, which is responsible for the "homing" of primitive hematopoietic stem cells. Evidence for this unique property of marrow stromal cells has been provided by the studies of Friedenstein et al,[20] which demonstrated induction of ectopic hematopoiesis in extramedullary sites by marrow-derived fibroblasts. Furthermore, the necessity of marrow stromal cells for the proliferation and differentiation of early hematopoietic stem cells has been shown in long-term marrow cultures. Prolonged hematopoiesis could not be maintained in the absence of a marrow-derived heterogenous adherent layer, which, as the marrow microenvironment cell population of the intact marrow, is composed of fibroblasts, endothelial cells, adipocytes, and macrophages.[21]

Limited information exists regarding the radiobiological properties of the human microenvironment. In experimental animals, irradiation has been shown to impair the hematopoietic supportive function of marrow stromal cells. Tavassoli[22] showed that irradiation with 500 rad of adherent layers of murine long-term marrow cultures resulted in loss of their ability to support prolonged hematopoiesis. Chamberlin et al[23] noted similar effects using a model of ectopic hematopoiesis. In this study, we have investigated the effects of in vitro irradiation on the survival and hematopoietic supportive function of human marrow stromal cells using the assays for

fibroblast colony-forming cells (CFU-F) and long-term marrow culture (LTMC), and a coculture assay that represents an in vitro model of marrow transplantation and includes nonirradiated hematopoietic cells and irradiated stromal layers. We demonstrate that the proliferative capacity of human marrow stromal progenitors, as well as that of their differentiated descendants, is quite sensitive to in vitro radiation, while the cell viability and hematopoietic supportive function of differentiated stromal cells are relatively resistant to the effects of radiation.

MATERIALS AND METHODS

Bone Marrow Cells

Bone marrow cells were obtained by aspiration from the iliac crest of healthy volunteers who gave informed written consent. Preservative-free heparin was used as an anticoagulant (Weddel Pharmaceuticals Ltd, London). Marrow buffy coat cells were collected after centrifugation of the aspirates at 200 g for ten minutes. Cells were then washed and resuspended in alpha modification of Eagle's medium (Flow Laboratories, Hamden, Conn) supplemented with 10% fetal calf serum (FCS; Sterile Systems, Logan, Utah).

To obtain marrow cells enriched for hematopoietic colony-forming cells, marrow buffy coat cells were separated into a buoyant and a dense fraction by neutral-density centrifugation in an isotonic sterile Percoll solution (1.074 g/mL, 270 mosm) (Pharmacia Fine Chemicals, Piscataway, NJ) as described elsewhere.[24] The buoyant mononuclear cells were subsequently subjected to two cycles of adherence in T-75 tissue culture flasks, at 37 °C, for one hour. Hematopoietic colony-forming cells contained in the nonadherent low-density (NAL) marrow cell fraction were collected, washed, and resuspended in culture medium

Culture Methods

Fibroblast colony-forming cell assay (CFU-F) The general procedure has been previously described.[25,26] Fibroblast colonies (50 or more cells per aggregate) were scored after ten days of incubation. The fibroblastic nature of cells composing the colonies was demonstrated by immunofluorescence staining with antibodies against fibronectin and types I and III collagen.[25]

Marrow fibroblast cell lines and passaged fibroblast colony-forming cell assay (CFU-F$_p$). Marrow cell suspensions were cultured as for CFU-F and maintained until a confluent fibroblastic layer was formed. Cultures were maintained with medium changes every four days. To passage primary or secondary fibroblast cultures, cell monolayers were washed twice with Ca^{++}- and Mg^{++}-free phosphate-buffered saline (PBS), covered with an EDTA-trypsin solution (GIBCO, Grand Island, NY), and incubated at 37 °C for ten minutes. Cells were then pipetted off, resuspended in medium containing FCS, washed twice, and subcultured in alpha medium supplemented with 10% FCS.

Colony formation by passaged marrow fibroblasts (CFU-F$_p$) was assessed by the method of Cox and Masson,[27] culturing low numbers of fibroblasts on lethally irradiated marrow fibroblast feeder layers (3,500 rad) Five to 10 × 10^3 cells resuspended in alpha medium supplemented with 20% FCS were inoculated into T-75 tissue culture flasks containing irradiated feeder layers, gassed with 5% CO_2 in air, and incubated at 37 °C. The growth medium was weekly changed Cultures were ended after 14 to 21 days of incubation, and colonies (50 or more cells) were counted after staining with Wright's stain

Granulocyte–macrophage colony-forming cell assay (CFU-GM) Granulocyte–macrophage progenitor cells were assayed using a slightly modified soft agar technique described by Pike and Robinson.[28] Colony formation was stimulated by 10% exogenously supplied colony stimulatory factors present in medium conditioned by human monocytic cell line GCT (GIBCO). Cultures were incubated at 37 °C in a humidified atmosphere of 5% CO_2 in air and scored for colonies (50 or more cells per aggregate) and clusters (three to 50 cells per aggregate) after seven days of incubation.

Long-term marrow culture technique Long-term cultures of human marrow were established according to the method of Gartner and Kaplan[29] with some modifications.[30,31] Briefly, 20 × 10^6 marrow buffy coat cells in 10 mL of LTMC medium were inoculated into T-25 tissue culture flasks. Cultures were then gassed with 5% CO_2 in air and incubated at 33 °C. The LTMC medium consisted of supplemented McCoy's 5A medium containing 12.5% horse serum, 12.5% FCS, and 10^{-6} mol/L hydrocortisone sodium succinate (Calbiochem-Behring, La Jolla, Calif). On day 4 of incubation, in order to eliminate erythrocytes and mature myeloid cells, the nonadherent cells were gently aspirated out of the flasks and enriched for mononuclear cells by Percoll neutral-density centrifugation. The resulting buoyant mononuclear cell-enriched fraction was collected, washed twice, resuspended in 5 mL of LTMC medium, and reinoculated into the original flasks containing the adherent stromal layers and fresh LTMC medium. The latter was added (5 mL per flask) soon after the nonadherent cells were aspirated out of the flasks. At weekly intervals, half the supernatant medium and suspension cells were removed and replaced with fresh LTMC medium. Cells in suspension were counted, checked for viability by trypan blue dye exclusion test, and assayed for CFU-GM.

To assess the kinetics of development of marrow stromal layers, individual LTMCs were examined every seven days under a phase contrast inverted microscope, and the percentage of the flask surface covered by the stromal interlocking network was visually estimated and recorded.

Cocultivation of marrow-derived stromal layers with freshly isolated autologous hematopoietic cells. To assess the capacity of established marrow stromal layers to sustain hematopoiesis in vitro, 4- to 6-week-old primary LTMCs were depleted of all suspension cells, and a second inoculum of freshly isolated autologous hematopoietic cells was added. This consisted of 6 × 10^6 NAL marrow cells resuspended in fresh medium. Cultures were then incubated at 33 °C and subsequently weekly depopulated and fed with an equivalent amount of fresh LTMC medium. Total cell counts and CFU-GM numbers were assayed in the removed cell population. To monitor the endogeneous CFU-GM production in primary cultures, the CFU-GM production in control cultures without added cells was also measured.

Immunocytochemical Analysis of Cultured Marrow Stromal Cells

To evaluate the composition of the stromal layers, we used immunofluorescence (IMF) methods with antibodies directed against components known to be associated with fibroblasts, endothelial cells, and macrophages as previously described.[24,29,30] These studies were performed in situ after the removal of the upper portion of culture flasks with a heated scalpel. Fibroblasts were identified by rabbit antibodies to type III collagen (kindly provided by Dr S Gay, University of Alabama, Tuscaloosa) and human fibronectin (Bethesda Research Laboratories, Gaithersburg, MD), endothelial cells by a rabbit antiserum to human factor VIII-related antigen (Calbiochem-Behring, San Diego), and macrophages by mouse monoclonal antibodies recognizing human monocyte antigens (Bethesda Research Laboratories) Lipid-containing cells were studied with oil red O staining.[32]

Irradiation Procedure

The Gammacell 40 irradiation chamber containing two opposing sources of cesium-137 (Atomic Energy of Canada Ltd, Ottawa) was used to irradiate marrow cell suspensions and cultured marrow stromal layers. The radiation was given as a single dose at the rate of 100 rad/min. During the time of irradiation, control samples were kept outside the Gammacell at the same temperature as the irradiated cultures. Marrow cells resuspended in serum-supplemented growth medium were irradiated with doses up to 600 rad and then assayed for CFU-F, CFU-GM, and LTMC. To assess the effect of irradiation on colony-forming cells, the mean number of colonies formed was used to calculate the plating efficiency and then the surviving fraction relative to the control values. Radiation dose–survival curves were then constructed on semilogarithmic paper Linear regression analyses of the curves were performed so as to yield the parameters of Do and n (the extrapolation number) To assess the effects of irradiation on stromal progenitors giving rise to adherent layers, marrow cells were irradiated and then inoculated for LTMC The kinetics of development and composition of stromal layers as well as cell and CFU-GM production were then weekly determined To assess any functional damage in stromal progenitors surviving irradiation, adherent layers derived from irradiated marrow cells were cocultured with freshly isolated autologous hematopoietic cells and assayed for their capacity to support prolonged CFU-GM production. To study the effects of irradiation on the stromal hematopoietic supportive capacity, established primary heterogeneous adherent layers (4 to 6 weeks old) were irradiated with doses up to 1,320 rad and then cocultured with freshly isolated hematopoietic cells. Subsequently, cell count, morphology, and CFU-GM production of the buoyant fraction were monitored weekly. In another set of experiments, secondary marrow fibroblast cultures were trypsinized, irradiated in suspension, and replated for colony formation in T-75 tissue culture flasks as described. The survival parameters (Do, n) were determined as described.

To assess the potential of cultured marrow fibroblasts to repair radiation-induced damage, we measured the ability of the surviving cells to grow in culture. Passaged marrow fibroblasts were irradiated in suspension and replated. Cultures were then passaged at weeks 1, 2, 5, and 6 after irradiation and plated at the same cell concentration (2×10^5 cells per flask) Between second and third passage, cells were left for a longer period (three weeks) to allow confluency The change in cell number, expressed as percentage of previous passage, was determined.

RESULTS

Effects of Irradiation on the Proliferative Capacity of Marrow Fibroblast and Granulocyte–Macrophage Progenitors

Cell survival curves for CFU-F and CFU-GM after in vitro single-dose irradiation are shown in Fig 1. Each point represents the mean of nine experiments for CFU-F and CFU-GM. Both survival curves show an exponential decrease in colony-forming ability with increasing radiation dose. A small initial shoulder is present only in the CFU-F survival curve. The parameters for survival curves are, for CFU-F, Do:130, n:1.3 and, for CFU-GM, Do:115, n:1.0. The morphology of fibroblast and granulocyte–macrophage colonies growing in cultures of irradiated cells did not differ essentially from that of colonies developing in cultures of control nonexposed cells.

Effects of Irradiation on the Proliferative Capacity of Cultured Marrow Fibroblasts

The cell survival curve for passaged marrow fibroblasts ($CFU\text{-}F_p$) after in vitro single-dose irradiation in cell suspension is shown in Fig 2. Each point represents the mean of three experiments. The survival curve is exponential and shouldered with a Do of 110 and n of 1.4.

The growth pattern of $CFU\text{-}F_p$ after different doses of in vitro irradiation is shown in Fig 2. Results are expressed as the percentage of change per previous passage and represent the mean of three experiments. Control nonirradiated marrow fibroblasts show an increase in number on each passage. Marrow fibroblasts irradiated with 480 and 720 rad exhibited a significant initial decrease in number, followed by rapid proliferation of the surviving cells. Irradiation with doses over 960 rad resulted in a decline of cell number in culture without a subsequent proliferation.

Establishment of Long-Term Cultures with Irradiated Marrow Cell Suspensions

The kinetics of development of marrow stromal layers and the CFU-GM production in long-term cultures derived from irradiated marrow cell suspensions are shown in Fig 3. Nonirradiated marrow cell suspensions were capable of establishing confluent stromal layers by the third or fourth week and of producing CFU-GM for five to seven weeks. Marrows irradiated with doses up to 240 rad established confluent stromal layers but were unable to produce any CFU-GM. A dose of 480 rad markedly impaired the establishment of stromal layers, and a dose of 600 or more rad abolished any stromal layer formation. This impairment could be overcome by a higher inoculum of irradiated marrow cells; the higher the radiation dose, the bigger the inoculum needed to establish a stromal layer (80×10^6 cells for 480 rad and 160×10^6 for 600 rad).

The composition of heterogeneous adherent layers derived from irradiated marrow suspensions is shown in Table 1. Control stromal layers were composed of fibroblasts, adipocytes, endothelial cells, and macrophages, with a clear predominance of fibroblasts. Stromal layers derived from marrows irradiated up to 240 rad had a similar composition to controls. Higher doses of radiation resulted in the establishment of only rare fibroblast islands.

Cocultivation of Stromal Layers Derived from Irradiated Marrow with Autologous Hematopoietic Cells

To analyze the functional capacity of stromal progenitors surviving irradiation, 4- to 6-week-old LTMC with stromal layers derived from irradiated marrows were cocultured with freshly isolated autologous NAL marrow cells. The hematopoietic function of these layers was assessed by quantifying every week the total cell and CFU-GM production. The summarized results of four experiments are shown in Fig 4 (SEM less than ± 10%). Control primary cultures without added fresh marrow cells did not produce any CFU-GM. Production of CFU-GM in cultures containing no stromal layers declined to undetectable levels by week 3. Stromal

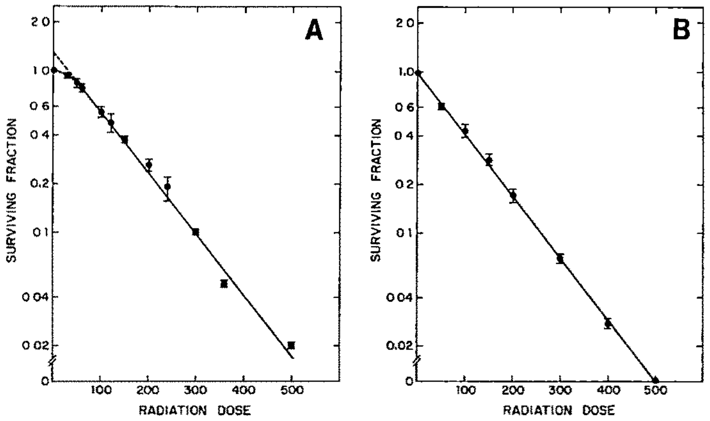

Fig 1. Cell survival curves for CFU-F (A) and CFU-GM (B). Marrow cell suspensions received a single-dose irradiation at the rate of 100 rad/min and were then assayed for colony-forming cells. Results shown represent the mean of nine experiments for CFU-F and CFU-GM. Survival parameters exhibited by CFU-F and CFU-GM were Do:130, n:1.3 and Do:115, n:1.0, respectively.

layers derived from nonirradiated marrow as well as those derived from irradiated marrows with doses up to 240 rad were capable of maintaining CFU-GM production for six to eight weeks. Doses of 480 or more rad severely impaired the establishment of stromal layers, and consequently, no prolonged hematopoiesis in the tissue culture occurred. However, confluent and functional adherent layers could be obtained when a higher inoculum of irradiated marrow cells was used.

Cocultivation of Marrow-Derived Stromal Layers Irradiated After Establishment with Autologous Hematopoietic Cells

To analyze the effects of irradiation on established marrow stromal cells, 4- to 6-week-old established stromal layers derived from nonirradiated marrows were subjected to radiation with doses up to 1,320 rad and then cocultured with freshly isolated autologous NAL marrow cells. The hematopoietic supportive function of these stromal layers was assessed weekly by total cell and CFU-GM production. Figure 5 summarizes the results of five experiments (SEM less than ± 10%). Control irradiated cultures without added fresh marrow cells did not produce any CFU-GM. The CFU-GM production in cultures with stromal layers exposed to 1,320 rad was similar to that seen in the cultures with nonirradiated stromal layers.

The composition of marrow-derived stromal layers irradiated after establishment is shown in Table 1. Irradiation with doses up to 1,320 rad did not affect significantly the composition of these adherent layers.

DISCUSSION

The data presented show that the proliferative capacity of human marrow stromal progenitors, as well as that of their progeny, is quite sensitive to radiation in vitro, while the viability and the hematopoietic function of differentiated marrow stromal cells are relatively resistant to the effects of radiation. The high radiosensitivity of marrow stromal progenitors is demonstrated by the parameters of CFU-F survival and the observations in LTMC showing a significant dose-related inhibition of stromal layer formation. Studies in experimental animals (mice, rabbits, guinea pigs) have shown that marrow fibroblasts are a crucial component of the marrow microenvironment. Cultured marrow fibroblasts transplanted under the kidney capsule generate ectopic hematopoietic microenvironments of donor origin that induce and sustain host-derived hematopoiesis in these sites.[20,33] By affecting the proliferative capacity of marrow fibroblasts, irradiation might damage their renewal potential, and therefore impair the hematopoietic function of the marrow microenvironment. In our study, the close Do values for CFU-F and CFU-GM indicate that fibroblastic progenitors are quite sensitive to in vitro radiation. Also, the

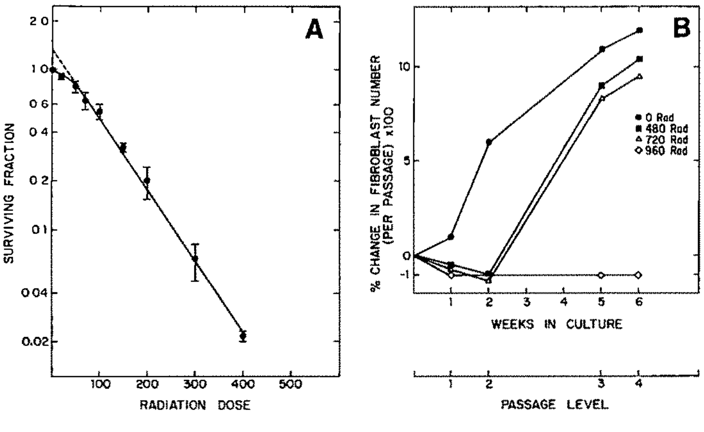

Fig 2. Survival curve (A) of passaged marrow fibroblasts (CFU-F$_P$) and the growth pattern (B) of the surviving cells after irradiation. Passaged marrow fibroblasts were irradiated in suspension and plated for colony formation. Results shown represent the mean of three experiments, showing a Do:110 rad and n:1.4. In another set of experiments, passaged fibroblasts were irradiated and then replated. After weeks 1, 2, 5, and 6, fibroblast number was determined before replating. The increase in fibroblasts number per passage, expressed as percentage of previous passage, was calculated and plotted. The results shown represent the mean of three experiments. Passaged marrow fibroblasts surviving irradiation up to 720 rad were able to proliferate and repopulate the tissue culture flask.

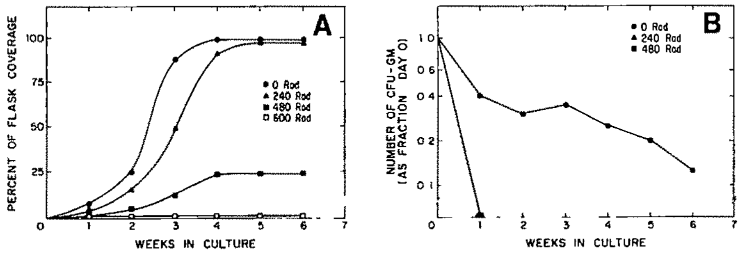

Fig 3. Kinetics of stromal development (A) and CFU-GM production (B) in LTMC derived from irradiated marrow cell suspensions. Marrow cells were irradiated and then inoculated for LTMC at the concentration of 20 × 10^6 per flask. Results shown represent the mean of four experiments. Note that relatively small doses of radiation abolish the long-term production of CFU-GM without impairing significantly the ability to give rise to a heterogeneous adherent layer.

proliferative capacity of passaged marrow fibroblast colony-forming cells (CFU-F_p) is highly radiosensitive. Comparison of our Do values for CFU-F with published data shows that our results are in the reported range.[34,35] Moreover, the Do value for both CFU-F and CFU-F_p is comparable to the Dos of 98 to 160 rad for other human fibroblastic cells of nonmarrow origin.[36] In addition to CFU-F, which represents only one cellular stromal element, we used the LTMC system to assess all the cells constituting the stromal cell population. Stromal cells derived from irradiated marrow cell suspensions failed to establish confluent adherent layers after relatively low doses of irradiation in a dose–response manner paralleling CFU-F and CFU-F_p survival curves. These observations in LTMC clearly show that all stromal progenitors are highly radiosensitive to in vitro irradiation.

The relatively similar in vitro radiosensitivity of marrow stromal and granulomonopoietic progenitors appears to be in discordance with in vivo findings,[14,37] which demonstrate a significantly higher radioresistance of stromal progenitors. Irradiation with doses used in human marrow transplantation ablates hematopoietic cells irreversibly but spares the stromal compartment, as evidenced by the occurrence of autologous stromal regeneration from residual stromal progenitors. An explanation for this apparent discrepancy could be that CFU-Fs are in vivo and in vitro in different phases of the cell cycle with different radiosensitivities. In intact marrow, the microenvironment is not a rapid proliferating compartment[25] in which most of the fibroblastic progenitors are most likely in G_0. In vitro, the growth factors present in the culture medium cause the entry of resting cells (G_0) into the proliferative phase (G_1), which has been shown to be highly radiosensitive.[38] An alternative or concomitant explanation for this discrepancy might be differences in the potential to repair sublethal radiation damage. In favor of this explanation is that CFU-F and CFU-F_p survival curves have a shoulder, which is absent in the survival curves for hematopoietic progenitors. In addition, the more efficient radiation repair mechanisms in vivo[39] may further contribute to the relative radioresistance of stromal cells in intact marrows. These differences in the repair mechanisms must be taken into account when extrapolating from in vitro observations to the cell in the intact organism.

Marrow stromal progenitors surviving in vitro irradiation are able to form normal functioning stromal layers. Coculture experiments have shown that stromal layers derived from irradiated marrow cell suspensions exhibited normal hematopoietic supportive function when a confluent layer was established. Marrow cells irradiated up to 240 rad gave rise to confluent stromal layers with normal hematopoietic support, while higher doses resulted in an impaired establishment. However, using a higher inoculum of irradiated marrow cells, we were able to obtain confluent stromal layers with normal hematopoietic supportive function. Thus a minimum number of surviving cells is required in order to establish a functional stromal layer. The latter finding might explain the process of marrow stromal renewal capacity after irradiation in vivo. The nonproliferative state and the repair potential of stromal cells enable the surviving stromal progenitors to maintain their proliferative capacity and, if an adequate fraction is left, reestablish a normal functioning stroma. Furthermore, experiments with passaged marrow fibroblasts have shown that these cells are able to recover and

Table 1. Cellular Composition of Irradiated Marrow Stromal Cells in Long-Term Marrow Cultures

	Relative Frequency						
	Stromal Layers Derived From Irradiated Marrow Suspensions*				Stromal Layers Irradiated After Establishment†		
Cell Type	Contr	240 rad	480 rad	600 rad	Contr	480 rad	1,320 rad
Fibroblast	4+	4+	1+	±	4+	4+	4+
Adipocyte	2+	2+	0	0	2+	2+	2+
End. cell	1+	1+	0	0	1+	1+	1+
Macrophage	3+	3+	0	0	3+	3+	3+

*Cultures were initiated with 20 × 10^6 irradiated marrow cells per flask. After four to six weeks of incubation, adherent layers were examined for their cellular composition. Irradiation with 480 rad impaired stromal establishment, and after 600 rad, only a few fibroblasts were present in culture.

†Cultures were initiated with 20 × 10^6 nonirradiated marrow cells per flask. Four to 6 weeks postinoculation the adherent layers were irradiated, and 24 hours later their cellular composition was evaluated. The cellular composition was assessed by immunofluorescence staining with antisera against type III collagen and fibronectin for fibroblasts, and against factor VIII-related antigen for endothelial cells, as well as monoclonal antibodies recognizing monocytic antigens, and by light microscopy for adipocytes. The presence and relative amount of different cell types was assessed semiquantitatively by grading their frequency from 0 to 4^+.

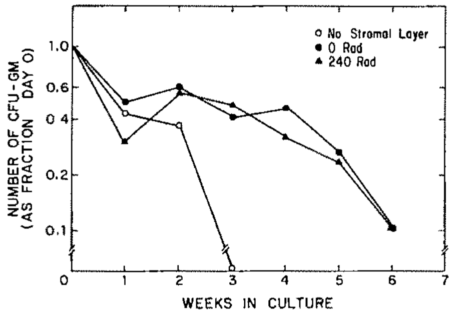

Fig 4. CFU-GM production in cocultures of stromal layers derived from irradiated marrows with autologous hematopoietic cells. Four- to 6-week-old stromal layers derived from 20 × 10^6 irradiated marrow cells were overlaid with 6 × 10^6 freshly isolated autologous NAL marrow cells. CFU-GM production was weekly monitored. Results shown represent the mean of four experiments. Marrow stromal progenitors that survive irradiation gave rise to stromal layers with normal hematopoietic supportive function.

undergo cell division after in vitro irradiation, as foreskin fibroblasts do.[40] These surviving fibroblasts that in vitro are capable of repopulating the tissue culture flask, in vivo might play a major role in stromal cell reconstitution after radiation-induced damage.

The hematopoietic supportive function of differentiated stromal layers is quite resistant to the effects of radiation, as shown by the coculture experiments. In vitro irradiation with doses in the range used in bone marrow transplantation does not impair the capacity of stromal layers to support prolonged granulomonopoiesis or their cellular composition. Although the curve of CFU-GM production may suggest that our coculture system is a declining one, detailed analysis of CFU-GM kinetics clearly shows that it supports active hematopoiesis. The culture flask can be viewed as a single compartment in which several phenomena occur simultaneously. In the absence of an adherent layer, there is no significant input of CFU-GM from an earlier compartment, whereas in the presence of an adherent layer, there is an active supply of CFU-GM by early progenitors. This explains the slower decline of CFU-GM frequency in cultures with adherent layers (six to eight *v* two to three weeks). The curves decline over time in both situations because the cell output exceeds the cell input. Cell output includes death, weekly demipopulation, and stem cell loss by differentiation. Data supporting active CFU-GM generation in this coculture system include (a) the six-week CFU-GM cumulative number in this study showing a higher CFU-GM content than in the recharge inoculum and (b) emergence of CFU-GM from earlier progenitors in cocultures of marrow cells depleted of CFU-GM by chemotherapeutic agents[41] or anti-Ia antibodies.[42]

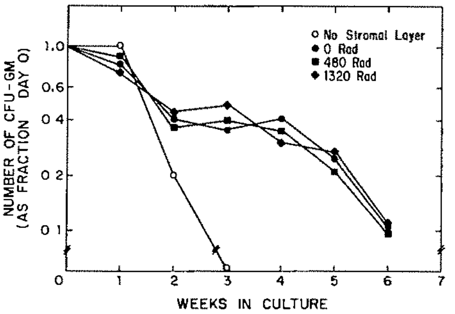

Fig 5. CFU-GM production in cocultures of irradiated confluent stromal layers with autologous hematopoietic cells. Four- to 6-week-old confluent stromal layers derived from nonirradiated marrows were irradiated and then cocultured with 6 × 10^6 freshly isolated autologous NAL marrow cells. CFU-GM production was monitored weekly. Results shown represent the mean of five experiments. Note that doses of irradiation up to 1,320 rad did not impair the hematopoietic supportive function of these layers.

The coculture system in which hematopoietic cells (donor cells) are added to established stromal layers (host stroma) reproduces in vitro the bone marrow transplant situation. Our in vitro observations parallel what occurs in human marrow transplantation. That donor hematopoietic cells engraft after irradiation of recipients with 1,000 rad[43] suggests that the hematopoietic supportive function of marrow stromal cells remains intact. Further evidence for the radioresistance of the hematopoietic supportive function has been provided by repopulation studies[14] showing active hematopoiesis in marrows that had been locally irradiated with doses up to 3,000 rad. It is of interest that in the murine system, a lower radioresistance of stromal function has been noted by some investigators,[22,23,44] while others observed a relatively radioresistant stromal function.[45] Whether these results represent different radiobiological properties or are due to the assay systems remains to be clarified. Our in vitro results in humans correlate well with in vivo observations showing an intact hematopoietic supportive function after irradiation with doses used for marrow transplantation.

Although it is well accepted that an intact marrow stroma is an absolute requirement for donor stem cell engraftment and sustained hematopoietic reconstitution, the role of host or donor stromal cells in this process in marrow recipients myeloablated with total body irradiation has not been clearly defined. This is in part due to the controversy regarding the origin and transplantability of the marrow stromal cells post marrow transplantation.[46-49] In any case, it appears that the host stroma plays a critical role in the early posttransplant period. Assuming that the marrow stroma is transplantable, it is unlikely that the donor stroma would both engraft and at the same time provide the conditions needed for donor stem cell "homing." Therefore, the host stroma has to provide the microenvironmental conditions until donor stromal cells populate the marrow and resume their hematopoietic supportive function. If nontransplantable, then the host stroma must maintain its normal hematopoietic supportive function and proliferative capacity to ensure, first, donor hematopoietic engraftment and, second, stromal reconstitution. Extrapolating our in vitro data to the marrow transplant situation, we can conclude that in the early stages of the posttransplant period, irradiated host mature stromal cells can provide the microenvironmental conditions needed for the seeding of donor hematopoietic stem cells and that host stromal cells retaining their proliferative capacity after irradiation can reconstitute the marrow stromal population.

Restricted Expression of a New Acute Myelogenous Leukemia–Associated Antigen (NHL-30.5) on Normal Hemopoietic Progenitor Cells

By David S. Askew, Allen C. Eaves, Connie J. Eaves, and Fumio Takei

We have previously reported the isolation of a monoclonal antibody (NHL-30.5) that reacts with an antigen expressed on a substantial proportion of marrow and blood cells of most patients with newly diagnosed or relapsing acute myeloid leukemia. This antigen is also found on several cell lines derived from myeloid malignancies of human origin. It is not present on mature hemopoietic cells or on the majority of differentiating bone marrow cells. In order to determine whether the NHL-30.5 antigen may, nevertheless, be expressed on low-frequency primitive normal hemopoietic cells, not detected in standard antibody screening procedures, its expression was studied on clonogenic erythropoietic and granulopoietic cells. Light-density (<1.077 g/mL) suspensions of normal or chronic myelogenous leukemia bone marrow and peripheral blood cells were stained with NHL-30.5 and fluorescein isothiocyanate labeled second antibody and then sorted into two fractions using the fluorescence-activated cell sorter. The first contained the top 5% of cells with the highest fluorescence intensity. The remainder were collected in the second fraction. Colony assays of both fractions showed the first to be enriched in CFU-E, BFU-E, and CFU-C content (fourfold to 17-fold). The second fraction was correspondingly depleted of these progenitors. These findings reveal NHL-30.5 antigen expression to be a transient event during normal hemopoiesis that characterizes primitive hemopoietic cells on several pathways. Subsequent experiments showed that the presence of up to 10 μg/mL of purified NHL-30.5 antibody in colony assay cultures neither inhibited nor stimulated colony formation. Marrow fibroblasts (subcultured marrow adherent cells) were NHL-30.5 negative. Immunoprecipitation studies showed that the antigen detected by NHL-30.5 is clearly distinct from that identified by My-10, another monoclonal antibody that has previously shown some similarities to NHL-30.5. It thus appears that the NHL-30.5 antibody reacts with a new myeloid differentiation antigen of as yet unidentified function that is normally restricted in its expression to early stages of hemopoiesis.

A VARIETY of circulating blood cell types are recognized by their unique morphological, antigenic, and functional properties. Current evidence indicates that the differentiation of these cells begins with the activation in primitive pluripotent progenitors of unique programs of gene expression that may take many cell generations to be completed.[1] The execution of such programs leads finally to the acquisition of specialized properties, although preliminary changes, including changes in responsiveness to various extrinsic growth factors, are also thought to occur. Some changes have been correlated with the loss of differentiative and proliferative potential that distinguish different populations of committed and pluripotent hemopoietic progenitors in clonogenic assays.[2] Nevertheless, there are relatively few examples of well-characterized intracellular or surface components that appear to be consistently altered during the earliest stages of hemopoietic progenitor differentiation.

One strategy for identifying relevant gene products is to prepare monoclonal antibodies against antigens that appear to be unique to leukemic cells.[3–9] This approach is based on the assumption that leukemic blasts may express surface antigens normally restricted to rare subpopulations of primitive hemopoietic cells. To enhance the selection of antibodies against such antigens, we raised monoclonals against HL-60 cell surface antigens and identified one (NHL-30.5) whose ability to bind to HL-60 cells was lost when these were induced to differentiate.[9,10] Subsequent studies showed that this monoclonal also reacted with a detectable proportion of blood and marrow cells from more than 80% of patients with newly diagnosed or relapsing acute myeloid leukemia (AML).[10] In contrast, mature blood cells, including granulocytes, lymphocytes, monocytes, and platelets, from either normal individuals or patients with chronic myelogenous leukemia (CML), were all found to be negative.[9] Similarly, by fluorescence-activated cell sorting (FACS) analysis, a detectable (>2%) positive population could not initially be demonstrated in buffy coat preparations of normal or CML marrow aspirates.[9]

Subsequent studies with light-density peripheral blood preparations from patients with CML revealed a small but clearly detectable NHL-30.5–positive population in some cases. A preliminary study with more highly purified populations of CML clonogenic granulopoietic progenitor cells also indicated that these reacted with NHL-30.5 (P.M. Lansdorp, personal communication, September, 1984). In this study, we have undertaken a more extensive evaluation of NHL-30.5 antigen expression on clonogenic progenitors, looked for a role of this antigen in progenitor cell proliferation and differentiation, and compared the antigens immunoprecipitated by NHL-30.5 and My-10.[7]

MATERIALS AND METHODS

Monoclonal antibodies The production of the NHL-30.5 monoclonal antibody, and its reactivity with normal and leukemic hemopoietic cells, has been described.[9] Hybridoma supernatant of the My-10 monoclonal antibody[7] was kindly provided by Dr Curt Civin (The Johns Hopkins Medical School, Baltimore).

Preparation of human cells Heparinized peripheral blood was obtained from patients with CML in established chronic phase. Normal marrow specimens were obtained from transplant donors or patients with malignancies that did not involve the marrow Informed consent was obtained in each case. The light-density fraction of all specimens was isolated on a 1.077 g/mL solution of Ficoll-Hypaque (LSM, Litton Bionetics, Kensington, Md), according to the recommendations of the supplier.

FACS analysis. Cells were stained for FACS analysis as previously described[9] and analyzed on a FACS 440 equipped with a logarithmic amplifier (Becton Dickinson, Sunnyvale, Calif). Control cells were reacted with fluorescein isothiocyanate (FITC)-conjugated antibody only. The FACS was routinely standardized, using glutaraldehyde-fixed chicken red blood cells and fluorescent microspheres. Debris was gated out on the basis of light scatter measurements. With this set up, we routinely detect B cells in the peripheral blood (5% to 15% population). In order to determine the progenitor recovery, the number of cells in each sorted fraction (from microscopic counts) was multiplied by the frequency of progenitors in the same fraction and divided by the number of progenitors present in the cell suspension before sorting. Calculated progenitor recoveries varied from 19% to 171%, with an overall mean of 78% ± 6%

Immunoprecipitation The iodogen procedure was used to label KG-1 cell surfaces, and antigens were precipitated as previously described [9] Immunoprecipitates were then analyzed by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE).

Assays for clonogenic myeloid progenitors. Cells were plated in standard 0.8% methylcellulose culture medium containing 30% fetal calf serum (FCS), 1% deionized bovine serum albumin, 10^{-4} mol/L 2-mercaptoethanol, 3 U/mL of human urinary erythropoietin (100 to 1,000 U/mg),[11] and 9% human leukocyte conditioned medium.[12] Normal unsorted bone marrow cells were plated at 1×10^5 cells per milliliter and peripheral blood at 4×10^5 cells per milliliter. Unsorted CML cells and all sorted cells were also plated at multiple lower cell concentrations to ensure obtaining a condition in which colony numbers were sufficient but not excessive. All evaluable cultures were scored and the data obtained consistent with a linear cell dose-colony yield relationship. Colonies derived from CFU-E (one to two clusters of erythroblasts) and mature BFU-E (three to eight clusters of erythroblasts) were counted on day 10 and from primitive BFU-E (more than eight clusters of erythroblasts) and CFU-C (more than 20 granulocytes and/or macrophages), on day 18, according to established criteria.[1]

For progenitor cell inhibition/stimulation studies, 1 to 10 μg/mL of purified NHL-30.5 monoclonal antibody was included in the assay medium. Assays both with and without erythropoietin and leukocyte conditioned medium were used in these experiments.

RESULTS

FACS analysis. Because the peripheral blood of patients with CML typically contains elevated numbers of progenitors,[13-15] CML blood was first used to investigate the expression of the NHL-30.5 antigen on these primitive cell types. Cells from four patients were studied. Depending on the patient, 1% to 11% of the Ficoll-Hypaque–separated CML cells were found to be NHL-30.5 positive. In the cases where <5% of the cells were positive, the sort gates were adjusted so that cells with the highest fluorescence intensity, constituting 5% of the total population, were sorted into the positive fraction and cells with the lowest fluorescence (the remaining 95%) were sorted into the negative fraction. Aliquots from both the positive and the negative fractions were then plated in standard methylcellulose assays. Table 1 shows the numbers of CFU-C, BFU-E, and CFU-E colonies per 10^5 cells measured in these experiments. In the positive fraction, granulocyte–macrophage progenitors were enriched an average of fourfold, while BFU-E and CFU-E were enriched sixfold and sevenfold, respectively. Both the enrichment of progenitors in the positive fraction and their corresponding depletion from the negative fraction were significant ($P < .05$, Table 1).

Ficoll-Hypaque–separated normal bone marrow and peripheral blood cells were than stained, sorted, and assayed

Three fractions were obtained: an NHL-30.5–positive fraction, an NHL-30.5–negative fraction, and an unsorted fraction Enrichment of all progenitors in the positive fraction and corresponding depletion from the negative fraction was significant when compared with the control in a one-tailed paired-sample t test ($P < .05$). Percentage of recovery was calculated as described in Materials and Methods

*Geometric mean (range defined by ± 1 SEM) in a similar fashion. Although a distinct NHL-30.5–positive population was not observed in either normal marrow or peripheral blood, the sort gates were adjusted in each case so that cells with the highest fluorescence intensity, again constituting 5% of the total population, were sorted into the positive fraction. Table 2 shows the results from experiments with six different normal marrow specimens. CFU-C were consistently and significantly ($P < .05$) enriched in the NHL-30.5–positive fraction (on average, approximately 17-fold). Significant ($P < .05$) enrichment of BFU-E and CFU-E was also demonstrated, with corresponding depletion of these progenitors from the negative fractions. Although the anomalous behavior of erythroid progenitors from bone marrow No. 3 (Table 2) suggests the existence of NHL-30.5–negative erythroid progenitors in this patient, the possibility that this result was an artifact cannot be ruled out. When the light-density mononuclear fraction of normal peripheral blood was sorted in a similar manner, the positive fraction again showed significant ($P < .05$) enrichment of all progenitor types: tenfold for CFU-C, fivefold for CFU-E, and fivefold for BFU-E (data not shown). Small numbers of CFU-GEMM (progenitors of mixed granulocyte–erythroid–macrophage colonies) were observed in some experiments where the general trend suggested a similar staining behavior to that of other clonogenic progenitors.

In some experiments, a control sample of cells was stained with the second antibody alone and the top 5% again sorted and assayed for progenitors. In such experiments, no enrichment of any progenitor type was obtained, thus providing direct evidence that the progenitor enrichment observed with NHL-30.5 staining was due to selective reactivity with this antibody.

To test whether marrow fibroblasts and other minor adherent cell components of normal marrow aspirates express NHL-30.5, marrow adherent layers were established in 20% FCS in alpha medium by seeding 1 to 2 × 10^7 cells into 60-mm tissue culture dishes and maintaining them at 37 °C with weekly feeding. After one or two subcultures, cells were allowed to reach confluence and then collagenased[16] before staining for FACS analysis. Such cell suspensions contained no detectable (<1%) NHL-30.5–positive cells (three separate marrows tested), whereas concurrently analyzed and collagenase-treated HL-60 cells were 40% positive.

Functional studies of NHL-30.5. Additional experiments were undertaken to investigate whether the NHL-30.5 antigen might be involved in progenitor proliferation or differentiation responses. To test these possibilities, purified NHL-30.5 antibody was incorporated into the assay medium (up to 10 μg/mL). This, however, had no detectable inhibitory or stimulatory effect on colony formation by normal peripheral blood or marrow progenitors by comparison with control cultures plated both with and without stimulators (erythropoietin and leukocyte conditioned medium) (three experiments, data not shown). Addition of an equivalent concentration of mouse Ig (Sigma Chemical Co, St Louis) was also without effect.

Immunoprecipitation. Because the pattern of reactivity of NHL-30.5 is most reminiscent of that observed with the My-10 monoclonal antibody,[7] both antigens were compared directly by immunoprecipitation of surface components of KG-1 cells. The KG-1 line was selected because the My-10 antigen is absent from HL-60 cells.[7] The proteins immunoprecipitated with these two antibodies were clearly different in their mobility in SDS-PAGE (Fig 1). The NHL-30.5 antigen was shown to have a molecular weight (mol wt) of 180,000 under both reducing and nonreducing conditions, as previously demonstrated for HL-60 cells.[9] My-10 precipi-

There was significant enrichment of all progenitors in the positive fraction when compared with the control fraction in a one-tailed paired-sample *t* test ($P < .05$). Depletion from the negative fraction was significant for both CFU-C and CFU-E but was not significant for BFU-E (experiments 3 and 5 were not depleted of BFU-E in the negative fraction). Percentage of recovery was calculated as described in Materials and Methods.

*Geometric mean (range defined by ±1 SEM)

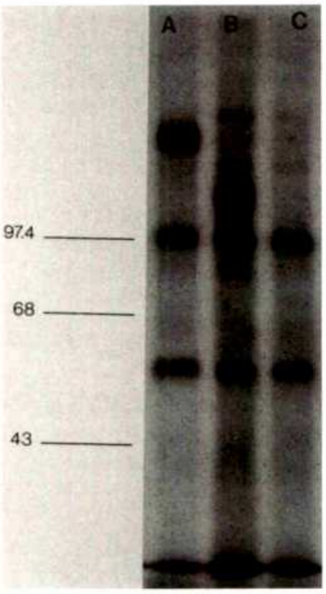

Fig 1. A comparison of the NHL-30.5 and My-10 antigens by immunoprecipitation. KG-1 cells were surface labeled with ^{125}I, and antigens were immunoprecipitated from the cell lysate, using the NHL-30.5 or My-10 monoclonal antibodies. Analysis was carried out on SDS-PAGE (7.5%) under reducing conditions. Lane A: NHL-30.5 monoclonal antibody; lane B: My-10 monoclonal antibody; lane C: negative control, an unrelated antibody raised against mouse lymphocytes.

tated a smaller moiety, with a mol wt of approximately 115,000 from the same cells.

DISCUSSION

The purpose of the study was to investigate the possible distribution of NHL-30.5 on uncommon but normal marrow elements whose presence would have escaped detection in standard binding studies or FACS analyses.[9,10] Such studies had shown that purified populations of lymphocytes, monocytes, granulocytes, erythrocytes, and platelets from normal individuals did not react with this antibody and that normal bone marrow buffy coat preparations contained less than 2% NHL-30.5–positive cells.[9] In the experiments described in this report, the light-density fraction of all specimens was obtained by centrifugation on Ficoll-Hypaque (density, 1.077 g/mL). This appeared to increase the number of NHL-30.5–positive cells by a few percent. As a result, a small but distinct (>5%) positive population could sometimes be demonstrated in the peripheral blood of CML patients in chronic phase. However, this was not the case for either normal marrow or peripheral blood samples, in which NHL-30.5–positive cells failed to reach the 5% level. Nevertheless, when cells with the highest fluorescence intensity (constituting 5% of the total population) were sorted and assayed, a significant and selective enrichment of clonogenic progenitors, including CFU-E and BFU-E as well as CFU-C, was obtained. These findings suggest that expression of NHL-30.5 is part of an early stage of hemopoietic cell differentiation that persists even after lineage restriction. In contrast to the positive results obtained with clonogenic progenitors, assessment of adherent marrow cell populations that are capable of regulating progenitor turnover in vitro (unpublished observations, June 1985) showed these to be NHL-30.5 negative.

Few monoclonal antibody reagents are currently available that identify antigens restricted in their expression to early stages of myeloid cell differentiation.[3,7,8] The My-10 monoclonal antibody[7] has a pattern of reactivity that shows some similarity to that of NHL-30.5 in that both react with immature myeloid populations and some leukemic blasts, but not with differentiated myeloid cells. The present study establishes that the antigen detected by My-10 is electrophoretically distinct from that detected by NHL-30.5. The former has an approximate mol wt of 115,000 in contrast to 180,000, the mol wt of the NHL-30.5 antigen. Consistent with this difference between My-10 and NHL-30.5 is the finding that NHL-30.5 reacts with cells from most (80%) patients with AML,[10] whereas My-10 appears to react with cells only from a minority (28%) of AML patients.[7]

The stage of normal hemopoietic cell differentiation at which NHL-30.5 first appears remains to be determined. Our limited observations to date suggest that clonogenic pluripotent progenitors (CFU-GEMM), like their various lineage-restricted but clonogenic progeny, are NHL-30.5 positive. However, even CFU-GEMM are not believed to represent stem cells with long-term repopulating potential. In standard short-term assays, most CFU-GEMM display limited self-renewal capacity[17-19] and thus differ from high self-renewal pluripotent cells that have recently been shown to be initially refractory to growth stimuli in vitro.[20,21] It was recently reported that the lineage-restricted progenitors observed in 4 to 6-week-old long-term marrow cultures may be derived from a population of cells that differ in HLA-DR expression from CFU-GEMM as well as CFU-C and BFU-E.[22] Experiments are currently under way to determine whether such differences also extend to NHL-30.5 expression.

The normal functional role of NHL-30.5 is also unknown. Because most clonogenic progenitors in normal peripheral blood are not actively cycling, in contrast to those in CML blood or all but the most primitive classes present in normal bone marrow,[23-27] it seems unlikely that regulation of NHL-30.5 expression is directly related to cell cycle status. Tests to evaluate whether NHL-30.5 binding could inhibit or stimulate normal progenitor proliferation and differentiation also showed no effect. Although this observation may reflect the particular epitope recognized by the NHL-30.5 antibody rather than the physiologic role of the antigen of which it is a part, surface functions other than those involved in colony formation need to be examined. The fact that deregulation of expression of the NHL-30.5 antigen appears to be a common event in AML may provide some clues in this regard.

ACKNOWLEDGMENT

We thank Giovanna Cameron, Dianne Reid, and Marjorie Hutchison for valuable assistance in hemopoietic cell culture, Wieslawa Dragowska for FACS analysis and cell sorting, and Michele Coulombe for typing the manuscript.

Activation of Human Granulocytes by Arachidonic Acid: Its Use and Limitations for Investigating Granulocyte Functions

By Harvey J. Cohen, Margaret E. Chovaniec, Kazuhiko Takahashi, and John C. Whitin

The effects of arachidonic acid on human granulocytes (polymorphonuclear neutrophil leukocytes, PMN) were examined with respect to early events associated with activation of the superoxide (O_2^-)-generating system and its reactivation with other stimuli after the addition of fatty acid–free bovine serum albumin. As with other stimuli, O_2^- production occurred after a lag that was dependent on the amount of arachidonic acid used. Although the lag, rate, and extent of O_2^- production were dose dependent, at all concentrations used, the duration of O_2^- production was four to six minutes. As previously described, when fatty acid–free albumin was added one minute after stimulation of PMN by arachidonic acid, O_2^- production ceased immediately. The O_2^--generating system could then be reactivated by the addition of either phorbol myristate acetate (PMA), concanavalin A, or serum-treated zymosan. In previously activated cells, the lag time for reactivation was shorter and the rate of O_2^- production greater with PMA. PMN membrane potential was depolarized by arachidonic acid. This depolarization was not reversed with the addition of albumin. PMN cytoplasts were also capable of reversible activation by arachidonic acid in a manner identical to whole cells. Divalent cations were found to be necessary for the activation of PMN by arachidonic acid. In the absence of calcium, arachidonic acid caused rapid lysis of the cells, as manifested by the release of lactic acid dehydrogenase. We were unable to measure later events in PMN stimulated by arachidonic acid since even in the presence of divalent cations lactic acid dehydrogenase was released from the cells after five minutes of incubation. We conclude that, in addition to its ability to activate PMN, arachidonic acid is toxic to the cells and cannot be used to study late events in granulocyte activity, and, in the absence of calcium, it may be difficult to interpret its action as a stimulant of the oxidase.

THE SUPEROXIDE (O_2^-)-generating system in human granulocytes (polymorphonuclear neutrophil leukocytes, PMN) appears to be a multicomponent enzyme complex consisting of one or more of the following components: flavoprotein,[1,2] cytochrome b,[3,4] ubiquinone,[5] and sulfhydryl groups.[6] The subcellular localization and translocation of these components has recently received much attention.[7–10] Resting PMN produce little[11] if any[12] O_2^-. Upon interaction with appropriate soluble and particulate stimuli, a complex series of events occur that include changes in membrane potential,[13,14] an increase in intracellular ionized calcium,[15,16] changes in cyclic nucleotides,[17] and the use of adenosine triphosphate (ATP).[18] These events accompany and some may be causally related to the activation of an NADPH oxidase, which results in the production of O_2^- and the other aspects of the respiratory burst.

The nature of the activation process is still largely unknown. Events such as phosphorylation,[19] proteolysis,[20] and protein translocation[9] have been postulated to be responsible for this activation. Curnutte et al have previously shown that O_2^- production by fluoride-treated PMN ceases when the cells are washed. O_2^- production could be reinstated with additional fluoride.[21] We have also shown that the activation of the O_2^--generating system by concanavalin A (Con A) can be reversibly inactivated with the addition of either α-methyl mannoside (α-MM) or tosylphenylalanylchloromethylketone.[22] Korchak et al have recently shown reversible activation by formylmethionylleucylphenylalanine (FMLP).[23] In this manuscript, we extend these observations on reversible activation using arachidonic acid as an activator of the PMN O_2^- generating system. Studies by other investigators have shown that arachidonic acid stimulation can be reversed with fatty acid–free bovine serum albumin.[24–25] We have investigated the nature of this reversible activation in both intact PMN and enucleated PMN or cytoplasts.[26] The similar results obtained in both systems eliminates certain processes in both the inactivation and reactivation of the PMN O_2^--generating system. We have, however, also found that archidonic acid produces irreversible damage to PMN that limits its use in investigating the latter aspects of the respiratory burst.

MATERIALS AND METHODS

Cytochrome c (type VI), superoxide dismutase, arachidonic acid (99% pure), cytochalasin B, Con A, α-MM, fatty acid–free bovine serum albumin, FMLP, *Micrococcus lysodeikticus*, NADPH, NADH, pyruvate, *p*-nitrophenyl phosphate, and Triton X-100 were purchased from Sigma Chemical Co, St Louis; Dextran T500, Ficoll-Paque and Ficoll 70 from Pharmacia Fine Chemicals, Piscataway, NJ; phorbol myristate acetate (PMA) from Consolidated Midland Chemical Co, Brewster, NY, 3,3′-dipropylthiodicarbocyanine (diSC_3-5) from Molecular Probes, Junction City, Ore; and zymosan from ICN Pharmaceuticals, Plainview, NY These and all other reagents were obtained at the highest level of purity and used without further purification. All surfaces in contact with cells were plastic or siliconized glass except for spectrophotometer cuvettes.

Preparation of PMN. Peripheral blood was collected in acid-citrate-dextrose and PMN were purified by dextran and Ficoll-Paque sedimentation as described previously.[27] The cells (95% to 98% PMN) were washed and suspended in phosphate-buffered saline (PBS)[28] at 2 to 5 × 10^7/mL All cells and enzymes were maintained on ice until used. Arachidonic acid was stored under vacuum in sealed vials at a concentration of 10 mg/mL in ethanol and was diluted to 2.5 mg/mL with water and clarified with 0.1 N NaOH prior to use. High-performance liquid chromatography (HPLC) analysis of the stored arachidonic acid demonstrated that there were less than 1% oxidation products of arachidonic acid The

ability of arachidonic acid to stimulate PMN did not vary during the course of the day's experiments.[24] PMA,[29] Con A,[22] and serum-treated zymosan (STZ)[30] were prepared as previously described.

Preparation of cytoplasts. Neutrophilic cytoplasts were prepared as previously described.[26] PMN were suspended in a 12.5% (wt/vol) Ficoll 70 solution containing 10 μg/mL of cytochalasin B and heated for five minutes at 37 °C. The suspension was layered on a prewarmed, discontinuous gradient of 16% (wt/vol) and 25% (wt/vol) Ficoll 70. Cytochalasin B (10 μg/mL) was present through the gradient. The gradients were centrifuged for 30 minutes at 81,000 g (middle of the tubes) at 33 °C. After centrifugation, the cytoplasts were harvested at the interface of the 12.5% and 16% Ficoll solutions. The cytoplast fractions were washed five times with PBS by centrifugation for ten minutes at 800 g at 20 °C. As a control, granulocytes were incubated with 12.5% Ficoll 70 and 10 μg/mL cytochalasin B for 30 minutes at 33 °C and washed five times with PBS. Alkaline phosphatase as a marker of the plasma membrane was measured by the method of Roos et al.[26]

Assay for O_2^- production Continuous spectrophotometric measurements of O_2^--dependent cytochrome c reduction was performed as previously described[29] in a Varian DMS 100 double-beam spectrophotometer with a water-jacketed cell compartment set at 37 °C. The sample cuvette contained ferricytochrome c (100 nmol), PMN (1 to 2.5 × 10^6), or equivalent amounts of cytoplasts and the appropriate stimulant In addition, the reference cuvette contained superoxide dismutase (20 μg). Lag times were recorded as previously described,[12] with the chart recorder started at the time of the addition of the stimulant to the sample cuvette.

Membrane potential depolarization. PMN membrane potential changes induced by arachidonic acid could not be continuously monitored using fluorescent probes as we had previously done in studies of PMA-,[13] STZ-,[30] and Con A-[31] induced depolarization. Addition of arachidonic acid to cell-free carbocyanine dye in buffer resulted in complete quenching of its fluorescence. This effect was reversed by the subsequent addition of albumin. The quenching problem was circumvented by exploiting the ability of albumin to rapidly bind arachidonic acid. PMN were incubated with arachidonic acid in microcentrifuge tubes for varying lengths of time Albumin was then added and the incubation continued for a total elapsed time of two minutes for all samples. At that time, the samples were centrifuged for 5 seconds, the supernatant discarded, and the cells resuspended in Krebs Ringer Phosphate ([KRP] PBS plus 1 mmol/L $CaCl_2$ and 1.2 mmol/L $MgSo_4$). The membrane potential of these cells was then assessed by incubating them at 2 × 10^6/mL with 2 μmol/L $diSC_3$-5 for seven minutes and measuring the fluorescence in a Perkin Elmer Model 650-10S spectrofluorometer

Degranulation. Cell suspensions (1 × 10^7/mL) were incubated with arachidonic acid at various concentrations, Con A (100 μg/mL), or PMA (1 μg/mL) for the times noted. For the arachidonic acid-treated cells, albumin (1.4 mg/mL) was added at various times. In each instance, the cells were centrifuged in a microcentrifuge for one minute and the supernatants assayed for lysozyme and lactate dehydrogenase (LDH) activity. Lysozyme activity was measured at 450 nm by following the lysis of *Micrococcus lysodeikticus* as previously described.[32] LDH activity was measured by the continuous spectrophotometric method of Beutler.[33] Whole cells were lysed with 0.05% Triton X-100 and assayed for total enzyme content using the equivalent of 2 to 4 × 10^5 PMN per assay.

RESULTS

Arachidonic acid–stimulated superoxide production. Previous investigators have shown that addition of arachidonic acid to PMN stimulates O_2^- production.[24] It has been stated that this superoxide production occurs without a lag time following the addition of arachidonic acid.[25] As can be seen in Fig 1, there is a definite lag time prior to complete activation of the O_2^--generating system by arachidonic acid. We have found that this lag time is 15 to 30 seconds at 37 °C. The duration of superoxide production by arachidonic acid–stimulated PMN is quite short, terminating in three to five minutes. O_2^- production in these samples could not be restored by the addition of either more PMN or more arachidonic acid. The rapid termination of O_2^- production was not due to the release of toxic substances from the PMN since the addition of both fresh PMN and arachidonic acid to the samples resulted in a resumption of O_2^- production after the appropriate lag. This was true even when the fresh PMN were allowed to incubate for up to six minutes in the assay cuvettes containing the original cells and arachidonic acid prior to the second addition of arachidonic acid. As can also be seen in Fig 1, the duration of O_2^- production by arachidonic acid is unaffected by the rate or extent of O_2^- production. At a lower concentration of arachidonic acid both the rate and extent of O_2^- production are diminished, but the duration of the burst is the same as for the higher concentration of arachidonic acid. Neither the rate nor the duration of O_2^- production by arachidonic acid is affected by the addition of cytochalasin B. The lag time for arachidonic acid is shorter than for most stimuli but is still dependent, as is the rate, on the concentration of arachidonic acid used to activate the cells, as shown in Fig 2.

Reversibility of arachidonic acid–induced superoxide production. It has previously been shown that the addition of albumin to arachidonic acid–stimulated PMN resulted in an immediate cessation of O_2^- production.[24] The addition of more arachidonic acid then resulted in a reinstitution of O_2^- production. O_2^- production can be reinstituted in PMN previously treated with arachidonic acid followed by albumin after the addition of either PMA, STZ, or Con A. Figure 3 demonstrates that the maximum attainable rate of O_2^- production induced by PMA is the same whether or not the cells were previously activated with arachidonic acid. At lower, nonsaturating concentration of PMA, the rate of O_2^- production induced by PMA is greater and the lag times are shorter when the PMN had previously been stimulated with arachidonic acid. These results are similar to our previous

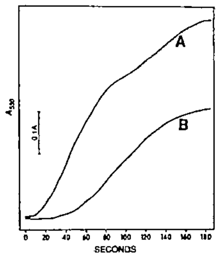

Fig 1. O_2^- production by arachidonic acid–stimulated PMN. Superoxide dismutase–inhibitable O_2^- production by 1 × 10^6 PMN in KRP was monitored (as the change in absorbance) at 550 nm of cytochrome c in a double-beam spectrophotometer as described in the Methods section in the presence of (A) 25 μg or (B) 6.3 μg of arachidonic acid added at zero time. Although the lag time, rate, and extent of O_2^- production were different, the duration of O_2^- production was the same at each concentration.

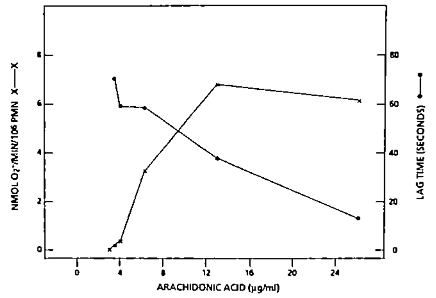

Fig 2. Effect of arachidonic acid concentration on PMN O_2^- production. Arachidonic acid, at the concentrations noted, was added to PMN, and the initial linear rates of O_2^- production (×) and lag times for O_2^- production (●) were measured at 37 °C. The results are the average of duplicate determinations.

findings in Con A– and α-MM–treated PMN and indicate that previously activated PMN are primed for reactivation with a shorter lag and an increased sensitivity to the second stimulus.

Membrane potential depolarization by arachidonic acid. The membrane potential of cells treated with arachidonic acid and albumin was assessed using the fluorescent dye diSC$_3$-5 as described in the Methods section. The results, as shown in Fig 4, indicate that depolarization appears to begin within 5 seconds after interaction of the cells with arachidonic acid. The maximum extent of depolarization appears to occur after 30 seconds. This correlates with the time necessary for activation of the O_2^--generating system by arachidonic acid. As has previously been shown for α-MM treatment of Con A–stimulated PMN,[31] inactivation of the O_2^--generating system by albumin does not reverse the depolarization.

Time course for reactivation. As previously noted, the duration of O_2^- production induced by arachidonic acid is short and is not affected by treatment of PMN with cytochalasin B. We examined reactivation of arachidonic acid–treated PMN by PMA as a function of the time between the addition of arachidonic acid and albumin. The ability of PMA to reactivate PMN treated with arachidonic acid and albumin decreased with time, and the cells could not be reactivated by PMA when albumin was added five minutes after arachidonic acid (when arachidonic acid–induced O_2^- production had ceased). Similar results were obtained when STZ or Con A were used as second stimuli. In addition, even when albumin was added to PMN after only a short incubation with arachidonic acid, there was a time-dependent effect on the ability of these cells to be reactivated by PMA. When PMN were incubated with arachidonic acid for one minute prior to the addition of albumin, there was a time-dependent decrease in the ability of PMA to restimulate these cells, with the cells almost completely unresponsive after 30 minutes' incubation. This was in contrast to the results obtained with Con A as an initial stimulus followed by the addition of α-MM after two minutes. In this instance, PMA could restimulate these cells even after 30 minutes' incubation.

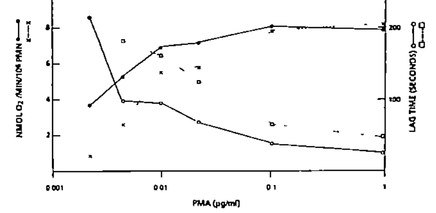

Fig 3. Effect of prior activation of PMN by arachidonic acid on responsiveness to PMA. PMN (1 × 10^6) were incubated in assay cuvettes with either arachidonic acid (12.5 μg) and albumin (1.4 mg) for two minutes prior to the addition of PMA (dashed lines) or arachidonic acid (12.5 μg) for one minute followed by albumin (1.4 mg) for an additional minute prior to the addition of PMA (solid lines). The rates of O_2^- production (×, ●) and the lag times (□, ○) are plotted as a function of the concentration of PMA used. The results are the average of duplicate determinations.

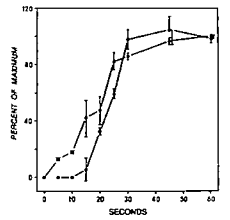

Fig 4. Comparison of arachidonic acid–induced membrane potential depolarization and rates of O_2^- production. Arachidonic acid (15.6 μg) was added to 2.5 × 10^6 PMN in 1.25 mL KRP, and at the indicated times albumin (1.75 mg) was added. The incubation was continued for a total of two minutes. The PMN were then rapidly centrifuged and resuspended in 0.25 mL KRP. These PMN (0.2 mL) were immediately added to 0.8 mL KRP and incubated with 2 μmol/L diSC$_3$-5. The steady-state level of fluorescence (a function of the membrane potential) was then recorded after seven minutes (●). An increase in fluorescence indicates membrane potential depolarization. In parallel experiments, the rate of arachidonic acid–stimulated O_2^- production was determined at the times noted (○) with the aid of a Varian DS-15 computer interfaced with the double-beam spectrophotometer. All results are given as the percentage of maximum values obtained at two minutes. The results are the mean and standard deviations of triplicate determinations.

Reversible activation of cytoplasts with arachidonic acid and Con A. PMN cytoplasts were prepared as previously described.[26] We compared the ability of arachidonic acid and Con A to activate these cytoplasts and the ability of second stimuli to reactivate these enucleated and granule-depleted cells. Figure 5 shows the ability of cytoplasts to respond to arachidonic acid and Con A. The rate of O_2^- production and the lag times when normalized to alkaline phosphatase content were similar for cytoplasts and PMN. The effects of albumin on arachidonic acid–induced O_2^- production and α-MM on Con A–induced O_2^- production by cytoplasts were identical to that seen for whole cells. Finally, reactivation of cytoplasts by a second stimulus, PMA, was the same for cytoplasts when compared with whole cells. Thus, granule-depleted cytoplasts are capable of undergoing reversible activation and reactivation in a manner similar to whole cells. In these experiments, cytochalasin B was added to the assay cuvettes to ensure maximal O_2^- production by Con A–stimulated cytoplasts. O_2^- production by arachidonic acid–stimulated cytoplasts did not require additional cytochalasin B.

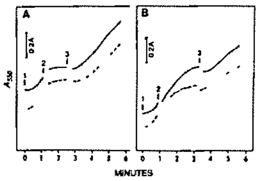

Fig 5. Reversible activation of cytoplasts by arachidonic acid and Con A. Cytoplasts were made as described in the Methods section. PMN (1 × 10^6) (solid lines) or the equivalent of 1 × 10^6 PMN as cytoplasts (dashed lines) were added to assay cuvettes in the presence of cytochalasin B (5 μg) and stimulated with (A) arachidonic acid (12.5 μg) or (B) Con A (100 μg). After one minute, albumin (1.4 mg) (A) or α-MM (25 μmol) (B) was added. After an additional one (A) or two (B) minutes, PMA (1.0 μg) was added to each sample. O_2^- production was monitored continuously after each addition.

Effects of divalent cations on arachidonic acid–dependent O_2^- production by PMN and cytoplasts. Most stimuli require external calcium for activation, but not for ongoing activity, of the PMN O_2^--generating system. We examined the calcium requirements for activation of PMN by arachidonic acid. Ethylene glycol tetra-acetic acid (EGTA), when added prior to the stimulant, prevented activation of PMN by arachidonic acid (data not shown), similar to what has previously been observed for most other stimuli. EGTA also prevented activation of the cytoplast O_2^--generating system by arachidonic acid (data not shown). Reactivation of PMN by second stimuli (with the exception of PMA) required the presence of divalent cations. When EGTA is added with albumin after stimulation of PMN with arachidonic acid prior to addition of either Con A or STZ, neither was capable of reactivating the O_2^--generating system. Reactivation of PMN by PMA was unaffected by the combined addition of EGTA and albumin. For Con A and STZ we have been able to demonstrate that EGTA has no effect on ongoing O_2^- production.[30,31] When EGTA was added to arachidonic acid–stimulated PMN, O_2^- production ceased immediately. However, these cells were incapable of responding to PMA, indicating that EGTA in the presence of arachidonic acid may have been toxic to the oxidase system. Similar results were obtained when arachidonic acid was added to PMN in the absence of divalent cations.

Effects of arachidonic acid on release of lysozyme and LDH. It has previously been reported that although O_2^- production by Con A– and FMLP-stimulated PMN can be reversed, degranulation continues.[23,31] We attempted to determine whether the same phenomenon occurred with arachidonic acid–treated cells. As can be also be seen in Fig 6, arachidonic acid stimulation of PMN resulted in the time-dependent release of lysozyme into the extracellular medium. As can also be seen in this figure, the addition of albumin at various times after stimulation by arachidonic acid did not completely prevent further enzyme release. We also compared LDH release by arachidonic acid–stimulated PMN with the release of lysozyme. Figure 6 also shows that after ten minutes significant amounts of LDH are also released and that at 30 minutes its release approaches that of lysozyme. The addition of albumin even one minute after arachidonic acid did not prevent further release of LDH. Thus, although it appears that lysozyme release occurs after O_2^- production ceases, we were unable to determine with certainty whether there was any specific release of granule contents following termination of O_2^- production with albumin. Lower concentrations of arachidonic acid (1 to 5 μg/mL) induced release of lysozyme without causing LDH release. However, these concentrations were not sufficiently high to activate the O_2^--generating system.

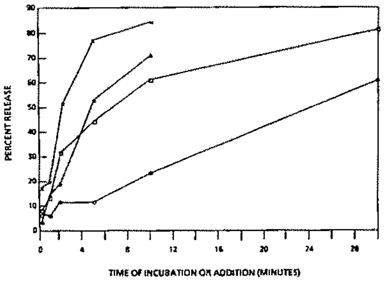

Fig 6. Arachidonic acid–stimulated lysozyme and LDH release and effect of albumin. Arachidonic acid (12.5 μg) was added to 2 × 10^6 PMN in KRP in a total volume of 1 mL. At the times noted, the cells were centrifuged for 10 seconds in a microfuge. The supernatant was then assayed for lysozyme (□) and LDH (○). To other PMN (2 × 10^6), arachidonic acid (12.5 μg) was added at zero time, and at the times noted, albumin (1.4 mg) was added. The incubations were continued for a total of 30 minutes, the cells centrifuged and the supernatant assayed for lysozyme (×) and LDH (△) content. The lysozyme and LDH content of PMN was determined and the results reported as the percentage of total cellular content of each enzyme released. The results are the average of duplicate determinations.

The effect of EGTA was further explored by examining lysozyme and LDH release at early (five-minute) and late (30-minute) times after the addition of arachidonic acid. As can be seen in Fig 7, for cells stimulated in KRP (A), lysozyme release after five minutes was greater than LDH release, with the two approximating each other after 30 minutes. In the presence of EGTA (B) or for cells stimulated in PBS (C), essentially maximal lysozyme and LDH release occurred within five minutes. Even when EGTA was added one minute after arachidonic acid (D), both lysozyme and LDH release occurred within five minutes. In other studies, we found that maximum LDH release occurred as early as two minutes after the addition of arachidonic acid to EGTA-treated cells. Figure 8 shows that it was the absence of Ca^{++} rather than Mg^{++} that resulted in this arachidonic acid–induced rapid lysis. No significant release of LDH occurred in PMN incubated in EGTA in the absence of a stimulus or in the presence of PMA (1 μg/mL) or Con A (100 μg/mL) and cytochalasin B (5 μg/mL). It therefore appears that in the absence of Ca^{++} arachidonic acid is rapidly toxic to PMN.

DISCUSSION

It has previously been reported that arachidonic acid activation of PMN results in the immediate onset of O_2^- production.[24,25] This was in contradistinction to all other stimuli, which induce O_2^- production after a lag time of 30 to 60 seconds. We examined this measure of activation at 37 °C in a continuous assay and found a short (15 to 30 second),

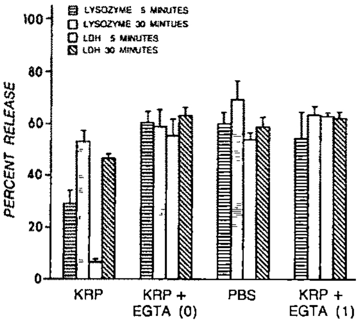

Fig 7. Effect of divalent cations on lysozyme and LDH release by arachidonic acid–stimulated PMN. As indicated on the x-axis, arachidonic acid (12.5 μg) was added to 2 × 10^6 PMN in KRP, KRP + 10 mmol/L EGTA (at time zero), or PBS. After five and 30 minutes, the cells were centrifuged and the supernatants assayed for lysozyme and LDH content. In the last condition noted on the x-axis, 10 mmol/L EGTA was added one minute after the arachidonic acid and the cells assayed for lysozyme and LDH release at five and 30 minutes. All results are expressed as the percentage of total cellular content of each enzyme released and are the mean and standard deviation of quadruplicate samples.

reproducible lag time for arachidonic acid that was dependent on concentration. This lag time appeared to correlate with the time necessary for maximal membrane potential depolarization. The uncertainty about this statement is the result of the assay necessary to measure the membrane potential change induced by arachidonic acid. If albumin is able to immediately halt depolarization as it is able to stop O_2^- production, then the times shown in Fig 5 are correct. If there is a delay prior to halting depolarization, then the maximal membrane potential change may occur at a later time then noted. Since there are demonstrable differences between the early time points, it is unlikely that there is a significant delay between the addition of albumin and the cessation of the membrane potential change. We have confirmed the reversibility of the activation of the O_2^--generating system by arachidonic acid with albumin and agree with Badway et al that it occurs within seconds.[24] Thus, although activation requires a lag time, inactivation of arachidonic acid–treated PMN occurs within 5 seconds (the time necessary to obtain the first measurements). This rate of inactivation is faster than that occurring when α-MM reverses the activation of Con A–induced O_2^- production[22] but is similar to that seen for the reversal of FMLP activation.[23] In all instances, reactivation with other stimuli can occur with a shorter, but still demonstrable, lag time.

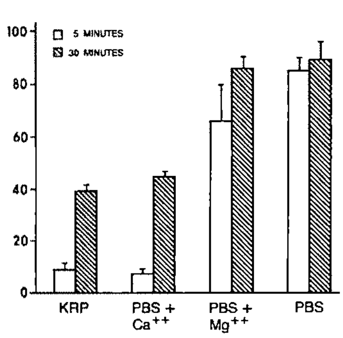

Fig 8. Effect of calcium or magnesium on LDH release by arachidonic acid–stimulated PMN. As indicated on the x-axis, arachidonic acid (12.5 μg) was added to 2 × 10^6 PMN KRP, PBS + 1 mmol/L Ca^{++}, PBS + 1.5 mmol/L Mg^{++}, or PBS. At five and 30 minutes, the cells were centrifuged for 10 seconds in a microfuge and the supernatants assayed for LDH content. All results are expressed as the percentage of total cellular LDH released and are the mean and standard deviation of quadruplicate samples.

PMN cytoplasts devoid of nuclei and deficient in granules have been used to study activation. We examined the reversible inactivation of cytoplasts by first stimulating them with arachidonic acid followed by albumin or with Con A followed by α-MM. The cytoplast response to these stimuli and inactivators was identical to that seen for whole cells. In addition, reactivation of cytoplasts was no different from that seen for whole cells. Thus, there appears to be no apparent role for ongoing degranulation in the reactivation of the O_2^--generating system by these stimuli.

In many ways, activation of PMN by arachidonic acid is similar to that by other stimuli. In addition, similar to FMLP, O_2^- production by arachidonic acid–treated PMN lasts only a few minutes. However, in contrast to FMLP, cytochalasin B does not enhance the rate or duration of O_2^- production.

We examined the phenomenon of early termination of the O_2^--generating system in detail. We found that the subsequent addition of PMN or arachidonic acid to the reaction mixtures did not result in additional O_2^- production. The addition of both fresh cells and fresh arachidonic acid did result in O_2^- production. The ability of arachidonic acid to activate fresh PMN, even after they had been incubated in the presence of previously activated cells for up to six minutes, indicates that the initial inactivation does not appear to be due to the release of toxic products into the medium. Thus, the early termination by arachidonic acid is probably due both to a depletion of the stimulus (perhaps by incorporation into the PMN) and an irreversible inactivation of the O_2^--generating system.

We also examined the ability of cells treated with arachidonic acid followed by albumin to respond to second stimuli. When albumin was added one minute after activation, O_2^- production could be reinitiated to nearly the maximum attainable rates by the addition of either PMA, Con A, or STZ. Thus, the cells retained their ability to respond to a second stimulus. We also found that, as the time between the addition of arachidonic acid and albumin increased, the ability of the cells to produce O_2^- with the addition of PMA or other stimuli decreased. If the albumin was added after four to five minutes when O_2^- production by arachidonic acid stimulated PMN had ceased, the second stimulus was ineffective at inducing additional O_2^-. This is consistent with the concept that arachidonic acid inactivates the oxidase, the same enzyme it activated. We also compared the effects of activation of PMN by arachidonic acid followed by albumin to PMN activated by Con A followed by α-MM. We activated the cells with the appropriate stimuli and inactivated the oxidase after one or two minutes with albumin or α-MM, respectively. When we added the second stimulus, PMA, at various times after the addition of Con A followed by α-MM, the O_2^--generating system could be reactivated for up to 30 minutes. However, PMN treated with arachidonic acid and albumin in this manner demonstrated a time-dependent inability to be reactivated by PMA. Thus, not only was the continued exposure of PMN to arachidonic acid toxic, but even a brief exposure resulted in a time-dependent inability to respond to a second stimulus.

These phenomena became clarified somewhat when we examined granule enzyme release induced by arachidonic acid. Arachidonic acid–treated PMN released lysozyme in a time-dependent manner. As had been shown for Con A and FMLP, despite reversible inactivation of the O_2^--generating system with arachidonic acid, the addition of albumin did not prevent further release of this enzyme. However, in contrast to Con A–treated PMN, LDH release also occurred. Only for low concentrations of arachidonic acid and for short periods of time was there a greater release of lysozyme than LDH.

Consistent with the aforementioned results are the observations of Badway et al that arachidonic acid stimulation of PMN results in significant morphologic changes indicative of cell damage.[24] However, unlike their observations of morphologic reversibility with albumin, we found continuing evidence of cell damage, even after albumin addition.

The toxicity of arachidonic acid to PMN was further intensified by the addition of EGTA or in the absence of Ca^{++}. This effect of arachidonic acid needs to be kept in mind when analyzing the recent reports on the ability of arachidonic acid to activate the O_2^--generating system in cell-free systems.[34–36] Of note is that this activation occurs in the absence of Ca^{++} and, in one instance, was inhibited by Ca^{++}.[34] Thus, the mechanism of activation of whole cells by arachidonic acid may be very different from the mechanism of activation of cell-free systems. The role(s) of extracellular Ca^{++} in the mechanism of activation of PMN by arachidonic acid cannot be discerned at this time. The toxicity of arachidonic acid to PMN in the absence of Ca^{++} precludes completely evaluating its role.

O'Flaherty et al did not find either LDH or lysozyme release when they incubated PMN with arachidonic acid.[37] However, the highest concentration they used was 10 μmol/L, and they incubated their cells for only five minutes. The combination of the concentration and time used in their study may have precluded the possibility of finding either enzyme released. We were able to demonstrate both a concentration and time dependency on the release of lysozyme and LDH.

Naccache et al did find selective release of lysosomal enzymes from arachidonic acid and cytochalasin B–treated neutrophils at 1 to 100 μmol/L arachidonic acid.[38] They did not find any evidence for LDH release. They used rabbit peritoneal neutrophils, which may have different sensitivity to arachidonic acid. We have previously shown that elicited neutrophils have altered reactivity to phagocytic stimuli and inhibitors when compared with peripheral blood neutrophils.[39]

We conclude that arachidonic acid shares many of the characteristics of other activators of the respiratory burst, including the presence of a lag time, dependence on external calcium, reversibility of activation, and ability to activate cytoplasts. It appears, however, that even a brief exposure of PMN to arachidonic acid results in time- and dose-dependent irreversible damage to PMN. These results and others described previously preclude the possibility of using arachidonic acid to study the latter aspects of the respiratory burst and other late events accompanying stimulus-response coupling.

ACKNOWLEDGMENT

We are very grateful to Dr Barry Levine for routine HPLC analysis of arachidonic acid.

Red Cell Rheology in Stomatocyte-Echinocyte Transformation: Roles of Cell Geometry and Cell Shape

By Walter H. Reinhart and Shu Chien

The influence of the shape of the red blood cell during stomatocyte-echinocyte transformation on its deformability was studied by microsieving through pores with diameters of 2.6, 4.5, and 6.9 µm. A stomatocytic transformation was produced by chlorpromazine (0.02, 0.1, and 0.5 mmol/L) and an echinocytic transformation by sodium salicylate (7.5, 30, and 120 mmol/L). For spherostomatocytes, an increase in filtration resistance through 2.6 and 4.5 µm pores was observed, whereas for spheroechinocytes, a decrease in filtration resistance through 2.6 µm pores was found. Larger pores (6.9 µm) were not sensitive to those shape changes. The changes in deformability can be explained by the fact that the surface area of (sphero)-stomatocytes decreased, whereas that of (sphero)-echinocytes increased; the cell volume remained essentially constant. Echinocytes produced by 24-hour adenosine triphosphate depletion differed from drug-induced echinocytes: they had an increased cell volume at constant surface area and consequently an increased filtration resistance through 2.6- and 4.5-µm filter pores. Shape changes with spicule formation are therefore not a homogeneous entity, and cell geometric factors (eg, surface area and volume) must be assessed with care. The viscosity of red cell suspensions at a hematocrit level of 45% was higher for drug-induced echinocytes than discocytes or stomatocytes at all shear rates tested. We conclude that the normal discocyte represents an optimum shape for the flow in vivo since a stomatocytic transformation could impair the passage through the microcirculation (decrease in cell filterability) and an echinocytic transformation could impair the flow in larger vessels (increase in blood viscosity).
© 1986 by Grune & Stratton, Inc.

THE SHAPE of a normal red blood cell (RBC) is that of a biconcave discocyte It is well recognized that this shape represents an equilibrium state between two opposing extremes of red cell shapes, ie, the stomatocyte and the echinocyte.[1] Red cells can easily undergo either transformation in vitro under the influence of certain agents.[1] These changes are reversible upon the removal of the causative agent or the addition of an antagonist.[1] A stomatocytic transformation is characterized by a tendency of membrane internalization and echinocytic transformation by membrane externalization. It has been suggested that stomatocytic transformation could be caused by a preferential incorporation of the causative agent in the inner hemileaflet of the membrane bilayer and echinocytic transformation by a predominant incorporation in the outer hemileaflet.[2] The red cell volume remains virtually unaltered[3] in both types of transformation.

This stomatocyte-discocyte-echinocyte equilibrium provides a unique in vitro model system to study the influence of RBC shape on the rheologic behavior of blood. The flow properties of blood in large vessels are governed primarily by the hematocrit level, plasma viscosity, RBC aggregation, and RBC deformability, which are the major determinants of whole blood viscosity.[4] The flow of blood in capillaries is primarily dependent on the deformability of the blood cells, which allows RBCs with a diameter of 8 µm to pass through channels with a diameter of 4 to 5 µm. The deformability of RBCs in such narrow channels is determined by the cell geometry, ie, the surface area/volume ratio or sphericity of the RBCs, the viscosity of the cytoplasm, and the biophysical properties of the cell membrane (which can be assessed by micropipette technique).[4] An in vitro test that can be used to assess the ability of red cells to pass through narrow channels is the filterability measurement by microsieving.[5,6]

We used filters with different pore sizes to study the influence of stomatocyte-echinocyte transformation on RBC deformability. The ultimate aim of the study was to obtain results from this in vitro model that allow further investigation of hematologic disorders with an abnormal RBC shape, eg, acanthocytosis, elliptocytosis, spherocytosis, etc.

MATERIALS AND METHODS

Blood was drawn from healthy young volunteers into vacutainer tubes containing 20 United States Pharmacopeia U/mL sodium heparin. After centrifugation at 1,000 g for ten minutes the plasma, buffy coat, and the uppermost RBC layer were removed. The RBCs were washed three times in Ringer's solution containing 0 85 g/dL NaCl, 0.03 g/dL KCl, 0.033 g/dL $CaCl_2$, 0.1 g/dL dextrose, and 0.5 g/dL bovine serum albumin, buffered to pH 7.4 with 0.1 N Tris (final Tris concentration about 0.005 N). Ringer's solution was prefiltered through 0.2-µm Millipore membranes before use. The washed RBCs were resuspended in Ringer's solution at a hematocrit value of 10.0%. The hematocrit value was determined in duplicate by the microhematocrit method. RBC and residual WBC counts were determined with an electronic particle counter (Coulter Counter Model ZB, Coulter Electronics, Hialeah, Fla). For the assessment of hemolysis, the RBC suspensions were centrifuged and the light absorption of the supernatant measured in a spectrophotometer at 540 nm. Reference values were obtained from the same amount of RBCs in distilled water (100% hemolysis) and from cell-free Ringer's solution (0% hemolysis)

Fresh stock solutions of chlorpromazine hydrochloride (CP) and sodium salicylate (SA) were prepared for every experiment The stock CP solution contained 1.5 mmol/L CP in Ringer's solution, with an osmolality of 300 mosm/kg H_2O and pH adjusted to 7.1 with 0.1 N Tris (at higher pH CP was not well soluble); the stock SA solution contained 160 mmol/L SA in distilled water, with an osmolality of 290 mosm/kg H_2O and pH adjusted to 7.4 with 0.1 N Tris The RBC suspension (hematocrit, 10.0%) was divided into

several aliquots. The aliquots were centrifuged (1,000 g for two to three minutes) to sediment RBCs and generate Ringer's solution supernatant. A calculated amount of Ringer's solution was replaced by an equal volume of either stock solution to obtain CP concentrations of 0.02, 0.1, and 0.5 mmol/L (final pH, 7.3) and SA concentrations of 7.5, 30, and 120 mmol/L. These RBC suspensions were then incubated for 20 minutes at 37 °C and used immediately afterwards for all experiments.

For adenosine triphosphate (ATP) depletion experiments, blood was drawn into sterile, heparinized vacutainer tubes. One half of the sample was used immediately for control measurements on fresh RBCs; the rest was incubated at 37 °C for 24 hours. A 24-hour incubation at 37 °C has been shown to deplete the RBC completely of ATP.[7-9] Fresh and incubated blood samples were centrifuged, the plasma and buffy coat removed, and the RBCs washed three times and resuspended in Tris-buffered Ringer's solution without glucose and albumin (hematocrit, 10%).

The RBC morphology was assessed by scanning electron microscopy (SEM). The RBC suspensions were fixed in 1% glutaraldehyde in cacodylate buffer (pH 7.4, 4 °C), postfixed in 2% OsO_4, dehydrated in ascending ethanol series, air-dried, and coated with gold-palladium. The specimens were viewed at 25 kV in a scanning electron microscope (model JSM-35, Jeol USA, Inc, Peabody, Mass). Some samples were embedded in epon after fixation. Thin sections were prepared and stained with 2% uranyl acetate and lead citrate for transmission electron microscopy (TEM; Model EM 9, Carl Zeiss Inc, Oberkochen, West Germany).

Quantitative assessment of shape transformations was made by the investigator without any knowledge of the type of treatment. Scanning electron micrographs at a magnification of 1,000× were used. In each experiment an average of 150 cells were classified for each type of treatment. The general classification of Bessis[10] was applied with some additional criteria. The stomatocytic transformation was classified as follows: stomatocyte I, a cup-shaped RBC (or convex-concave RBC); stomatocyte II, RBC with a pronounced concavity; stomatocyte III, RBC with a deep concavity and a variable mouthlike distortion and/or pitlike membrane indentations; and spherostomatocyte, a spherical RBC with an irregular area of pits. The echinocytic transformation was classified as follows: echinocyte I, an irregularly contoured discocyte with up to five buckles visible on SEM; echinocyte II, a flat RBC with multiple spicules; echinocyte III, an ovoid or spherical RBC with 30 to 50 spicules; and spheroechinocyte, a sphere with multiple short and thin spicules.

Morphometric analysis was performed on transmission electron micrographs using standard methods.[11] For volume assessments the point-counting method was used, for surface areas the method of intercept counting.

The surface area of RBCs was assessed in a wet preparation by light microscopy (Nomarski Optics; magnification, × 6,925) by using a modified version of the method described by Chabanel et al.[12] The RBC suspension was placed between a glass slide and a coverslip. By adding water from one side, an osmotic gradient was generated in the suspension; as a result, RBCs ranging from the initial shape to various degrees of swelling and hemolysis could be observed along the osmotic gradient created. There existed a sharp interface between maximally swollen cells and cells already hemolyzed; the diameter of these spherical cells along that line of interface was measured and the surface area calculated. Using the mean corpuscular volume measured prior to swelling, the sphericity index[13] was calculated (sphericity index $= 4.84 \times V^{2/3}/A$, where V and A are the volume and surface area of the cell, respectively). A perfect sphere has a sphericity index of 1.0.

The RBC osmotic resistance was measured with a routine procedure.[14] The packing capacity of stomatocytes and echinocytes was studied by ultracentrifugation of RBC suspensions at 100,000 g for 15 minutes. This supernatant was replaced by 1% glutaraldehyde, followed by another centrifugation of 15 minutes at 100,000 g. After overnight fixation, the RBCs were processed for TEM.

Red cell filtration was performed as described elsewhere.[6] In brief, the RBC suspensions were placed in a glass syringe and pumped at a constant flow rate of 0.82 mL/min (Model 975, Harvard Apparatus Co, Inc, Millis, Mass) and a temperature of 37 °C through polycarbonate filters (Nucleopore Corp, Pleasanton, Calif) with different pore sizes. The filters had a diameter of 13 mm, a thickness of 13 μm, and nominal pore sizes of 3 μm (lot no. 62C1A70, mean ± SD pore diameter determined by SEM to be 2.6 ± 0.2 μm), 5 μm (lot no. 54C1D7, pore diameter 4.5 ± 0.6 μm) and 8 μm (lot no. 51C9A29, pore diameter 6.9 ± 0.8 μm). The filtration pressure during constant flow was measured on the upstream side close to the filter with a pressure transducer (model MP 45-14, Validyne Engineering Corp, Northridge, Calif) connected to an amplifier (Validyne, model MC 1-3) and a recorder (model 385, Linear Instruments Corp, Costa Mesa, Calif). Prior to the filtration of RBC suspensions, Ringer's solution containing the same concentrations of CP or SA was filtered to obtain the filtration pressure for suspending medium (P_o); the presence of CP or SA did not affect the P_o value. The initial pressure rise (P_i), which reflects the deformability of the RBCs in suspension,[15] was determined for the RBC suspensions. The relative filtration resistance of an individual red cell, β, was calculated as follows: $\beta = 1 + [(P_i/P_o) - 1]V/h$, where V is the fraction of the pore volume[16] occupied by the red cell and h is the fractional volume of RBCs in suspension.[6,16] This dimensionless parameter β, developed by theoretical modeling,[16] is the ratio of resistance in a pore bearing a RBC to that filled with buffer alone.

The viscosity of suspensions of RBCs in Ringer's solution containing the drug (CP or SA) was measured with a Couette viscometer,[17] ie, a rotational cylinder viscometer, at various shear rates from 0.1 to 208/s.

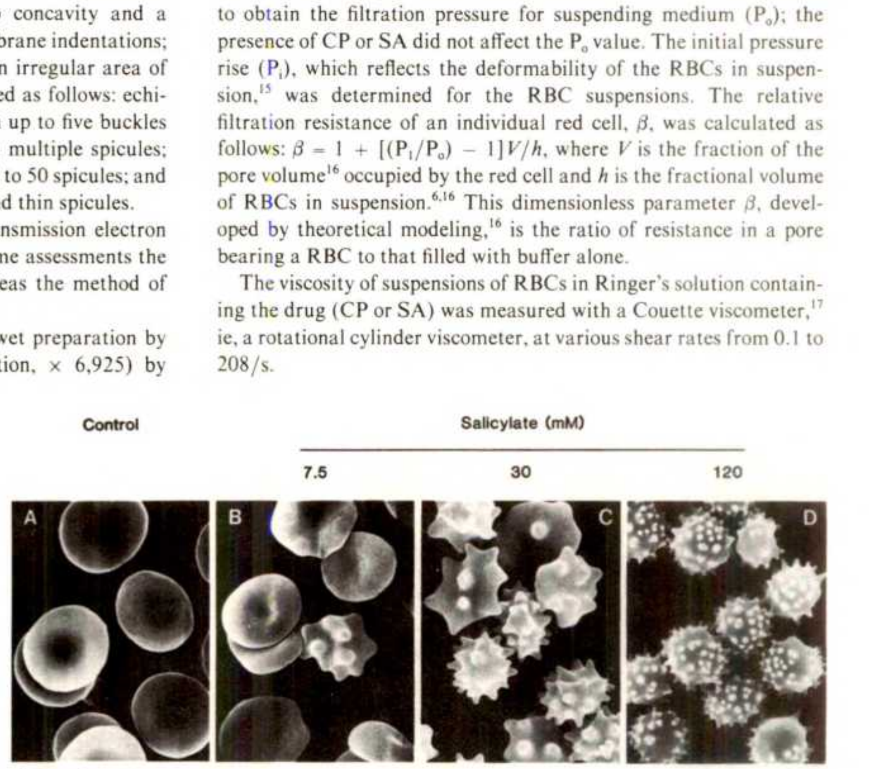

Fig 1. Scanning electron micrographs of RBCs undergoing echinocytic transformation induced by SA. (A) Normal discocytes. (B) SA, 7.5 mmol/L, with discocytes and echinocytes I. (C) SA, 30 mmol/L, with primarily echinocytes II. (D) SA, 120 mmol/L, with spheroechinocytes.

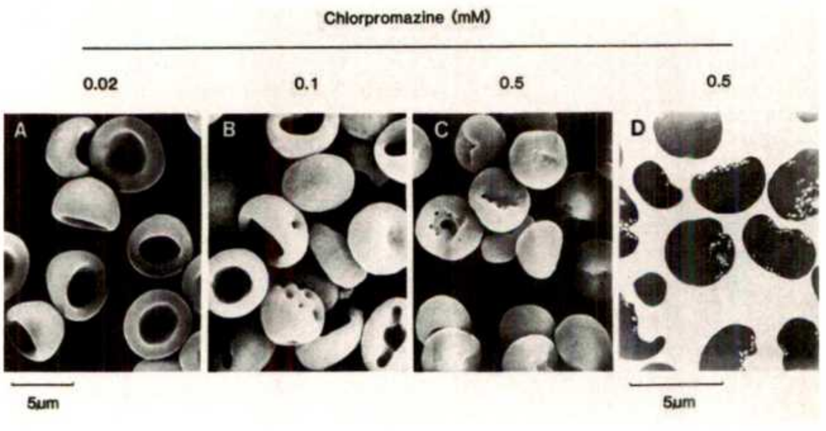

Fig 2. Scanning electron micrographs of red cells showing a dose-dependent stomatocytic transformation from stomatocytes I and II with 0.02 mmol/L chlorpromazine (A), to stomatocytes II and III with 0.1 mmol/L CP (B), and to spherostomatocytes with 0.5 mmol/L CP (C). (D) Transmission electron micrograph showing spherostomatocytes (0.5 mmol/L chlorpromazine) with multiple membrane-coated vacuoles within the cytoplasm.

For statistical analysis a one-way analysis of variance was used. Data on ATP-depleted RBCs were analyzed by Student's *t* test.

RESULTS

The morphologic changes of red cells after incubation with different doses of SA are shown in Fig 1. A concentration of 7.5 mmol/L SA had a discernible effect on red cell morphology (Fig 1B, discocytes and echinocytes I), 30 mmol/L SA induced a clear echinocytic transformation with predominantly echinocytes II (Fig 1C), and 120 mmol/L SA transformed the vast majority of red cells into spheroechinocytes (Fig 1D). The dose-dependent stomatocytic transformation obtained with chlorpromazine is shown in Fig 2. CP at 0.02 mmol/L generated mainly cup-shaped RBCs (Fig 2A), 0.1 mmol/L CP predominantly stomatocytes II and III (Fig 2B), and 0.5 mmol/L CP spherostomatocytes (Fig 2C). Spherostomatocytes had multiple intracellular vacuoles as seen by TEM (Fig 2D). When the extracellular marker ruthenium red[18] was added to the cell suspensions prior to embedding, the vast majority of the vacuoles (more than 95%) were ruthenium red–negative, indicating that these vacuoles were not in communication with the cell surface and the extracellular fluid. By morphometric analysis it was calculated that 3% of the total cellular volume was occupied by vacuoles. The degree of transformation was assessed in three to four different experiments by classifying the shape of 150 to 200 RBCs on SEM pictures. As shown in Table 1, the concentrations of the two antagonistic drugs chosen in this study cover the whole range of transformation from spherostomatocytes to spheroechinocytes. Spherostomatocytes and spheroechinocytes were not completely reversible, but lesser degrees of transformation fully recovered upon removal of the drug or by adding the antagonist.

Examples of pressure-time curves obtained for discocytes, stomatocytes, and echinocytes are shown in Fig 3. The filtration pressure curves obtained with 4.5-μm pores were not significantly affected by SA, even with the formation of spheroechinocytes in 120 mmol/L SA (Fig 3A). CP at concentrations of 0.02 and 0.1 mmol/L also did not have a significant effect on the filtration pressure curves with 4.5-μm pores, but at 0.5 mmol/L, CP elevated the pressure-time curve approximately fivefold. With 2.6-μm pores (Fig 3B), the slope of the pressure-time curve was more flat for echinocytes (30 and 120 mmol/L SA) and steep for stomatocytes (0.1 and 0.5 mmol/L CP). It is possible that the RBC passage did occur primarily through pores with a diameter larger than 2.6 μm (about 12% of the pores are >2.8 μm, ref 6). No differences were found for 6.9-μm pore filters (not shown). The initial pressure (P_i) was ascertained on these pressure tracings (Fig 3). For 2.6-μm pores and 0.5 mmol/L CP, the transition of the pressure-time curve (P_i) was not always clearly definable (Fig 3B); P_i was therefore defined for 2.6-μm pores as the pressure reading obtained 2 seconds after the onset of the pressure rise,[19] a time when P_i was normally found for other CP and SA concentrations.

The ratio β of the resistance in a pore bearing an RBC in transit to that in a pore with Ringer's solution alone was calculated. The results are shown in Figure 4. For the narrow

Table 1. Percentage of Red Cell Shapes

	Chlorpromazine (mmol/L)				SA (mmol/L)		
	0.5	0.1	0.02	0	7.5	30	120

Values are the mean ± SD.

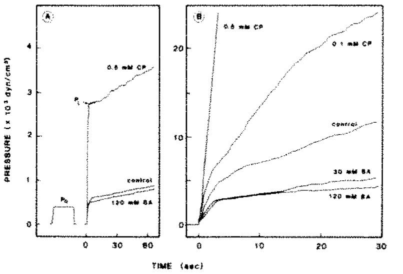

Fig 3. Pressure-time curves obtained for the filtration of suspensions with a fixed number of RBC ($0.98 \times 10^6/\mu L$) at a flow rate of 0.82 mL/min (resulting in a cell flux of 8×10^8 cells/min) through filters with a pore diameter of 4.5 μm (A) and 2.6 μm (B). Controls, stomatocytes (0.1 and 0.5 mmol/L CP), and echinocytes (30 and 120 mmol/L SA) are shown. P_0 is the pressure reading for Ringer's solution alone, P_i is the initial pressure for the RBC suspension.

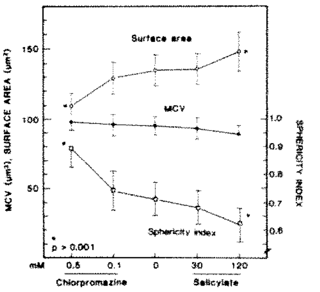

Fig 5. Geometric characteristics of stomatocyte-echinocyte transformation. The mean corpuscular volume (MCV, mean ± SD of six experiments), the surface area measured after swelling of the cells to obtain a spherical shape, and the calculated sphericity index for this experiment are shown for stomatocytes (0.1 and 0.5 mmol/L CP), discocytes, and echinocytes (30 and 120 mmol/L SA).

filter pores with a diameter of 2.6 μm, the increasing degree of (sphero) stomatocytosis induced by CP tended to increase the filtration resistance (β) of these red cells, whereas the increasing degree of (sphero-)echinocytosis induced by SA tended to decrease β; the changes being statistically significant at the highest concentrations of SA and CP used. Spherostomatocytes (0.5 mmol/L CP) also caused a significant increase in β for 4.5-μm pores, but filtration through 6.9-μm pores was insensitive to these shape changes.

Hemolysis in the suspensions before and after filtration was less than 1% for all shape transformations except spherostomatocytes (0.5 mmol/L CP) where hemolysis was 0.5% before filtration and 80% in the filtrate.

The geometric characteristics of stomatocytes and echinocytes are shown in Fig 5. The MCV showed a trend to be slightly higher in 0.5 mmol/L CP and slightly lower in 120 mmol/L SA as compared with discocytes; the difference was not statistically significant. The surface area of normal RBCs measured with our swelling method was 135 ± 12 μm^2; this agrees with the results of Linderkamp et al[20] who obtained 134 ± 14 μm^2 with the micropipette method. The RBC surface area was lower for 0.5 mmol/L CP and higher for 120 mmol/L SA. The intracellular vacuoles seen in spherostomatocytes (Fig 2D) may account for the loss in surface area. Spheroechinocytes, incubated at 135 mosm/kg H_2O for maximum swelling, were examined by TEM. It was found that all spicules were smoothened out by that procedure (not shown). The sphericity index was significantly higher for RBCs in 0.5 mmol/L CP and lower for RBCs in 120 mmol/L SA (Fig 5). This was confirmed by morphometric analysis of TEM pictures of spherostomatocytes and spheroechinocytes (not shown).

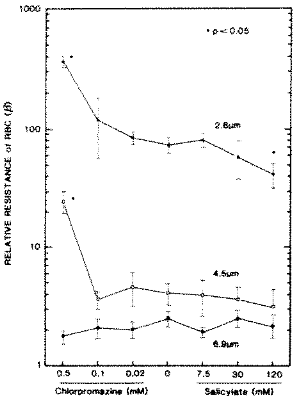

Fig 4. Semilogarithmic plot of the relative filtration resistance of an RBC (β) *v* different degrees of stomatocytic transformation (0.02, 0.1, and 0.5 mmol/L chlorpromazine) and echinocytic transformation (7.5, 30, and 120 mmol/L salicylate) for pore diameters of 2.6, 4.5, and 6.9 μm. The results represent the mean ± SD of four experiments.

The difference in sphericity between spherostomatocytes and spheroechinocytes is illustrated in Fig 6. Spheroechinocytes showed a capacity to deform in centrifugal packing, with the disappearance of spicules (Fig 6B), and the transmission electron micrographs of centrifugally packed spheroechinocytes are similar to those of the packed discocytes.[21] Packed spherostomatocytes were composed of undeformable spheres, and a significant degree of centrifugal packing was attained by the intercalation of less severely transformed cells that still had sufficient deformability to fit between the spheres (Fig 6A).

The relationship between cell surface area and volume was further tested by determining the osmotic resistance (Fig 7). The osmotic resistance was increased for echinocytes (30 and 120 mmol/L SA) and decreased for stomatocytes (0.1 mmol/L CP). For spherostomatocytes (0.5 mmol/L CP) complete hemolysis occurred above 0.6% saline.

The RBC morphology observed after metabolic depletion by incubating whole blood for 24 hours at 37 °C is shown in Fig 8A. The cell shape ranged from discocyte to echinocyte III. When these cells were washed and incubated in Ringer's solution containing 0.5 g/dL albumin, they regained a discoid shape (Fig 8B), which has also been observed by Ferrell and Huestis.[9] Sometimes the shape reversal even showed an overshoot, resulting in cup-shaped RBCs. Depleted RBCs washed and resuspended in buffered saline remained echinocytes (Fig 8C); the degree of echinocytic transformation became even more pronounced when the depleted RBCs were transferred from plasma to saline (Fig 8A). Fresh cells incubated in buffered saline for 20 minutes at 37 °C showed no echinocytic transformation (Fig 8D).

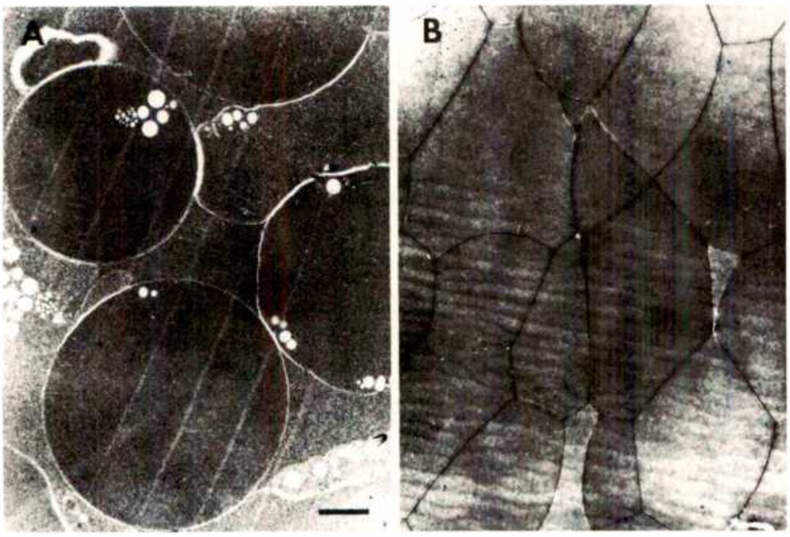

Fig 6. Transmission electron micrographs of (A) spherostomatocytes (0.5 mmol/L CP) and (B) spheroechinocytes (120 mmol/L SA) fixed with 1% glutaraldehyde during centrifugation at 100,000 g. Bar represents 1 μm.

The results of filtration studies on 24-hour–depleted RBCs washed and resuspended in Tris-buffered saline are shown in Fig 9. The relative filtration resistance (β) in 2.6-μm pores for the echinocytes induced by 24-hour depletion was more than twice as high as that for the discocytes from the same donor studied immediately after blood withdrawal. β was slightly but significantly increased for 4.5-μm pores also, whereas 6.9-μm pores were insensitive.

The geometry of the depleted RBCs is shown in Fig 10. The 24-hour depletion did not affect the surface area, slightly increased the cell volume, and therefore increased significantly the sphericity index ($P < .05$). These geometric results, as the filtration data, are in contrast to those obtained with drug-induced echinocytosis.

The morphology of RBCs was unaffected by the filtration procedure for stomatocytes as well as echinocytes (Fig 11). This indicates that despite the differences in filtration resistance there was no noticeable selective retention of cells with a higher filtration resistance by the filter and that the shape transformation is not altered after the mechanical shearing during filtration.

Neither drug affected the viscosity of the suspending medium alone (the same value of 0.75 CP for control, 0.5 mmol/L CP, and 120 mmol/L SA). Viscosity measurements of RBC suspensions in Ringer's solution (Fig 12) showed that spheroechinocytes (120 mmol/L SA) had a significantly higher viscosity than discocytes (control) and spherostomatocytes (0.5 mmol/L CP). The difference was more pronounced at low shear rates.

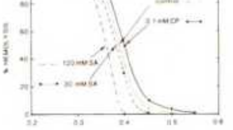

Fig 7. Osmotic resistance of discocytes (control), echinocytes (30 and 120 mmol/L SA), and stomatocytes (0.1 mmol/L CP). For spherostomatocytes (0.5 mmol/L CP), complete hemolysis occurred above the upper limit of 0.6% saline shown in this graph.

DISCUSSION

Stomatocytic and echinocytic transformations of red blood cells are dose dependent. The degree of transformation for a given drug concentration found in the present study agrees with previous reports.[3,22] The concentrations used for shape transformations are higher than the therapeutic plasma concentrations, which are about 0.001 mmol/L for chlorpromazine[23] and 2 mmol/L for salicylate.[24]

The stomatocyte-echinocyte transformation of RBCs affected their filterability through narrow pores. The sensitivity of the filtration test increased with decreasing filter pore size, which is in agreement with a previous study.[6] For a pore size of 2.6 μm, spherostomatocytic transformation (0.5 mmol/L CP) increased the filtration resistance, ie, decreased RBC deformability, whereas spheroechinocytic transformation (120 mmol/L SA) increased RBC deformability in this system. These changes in deformability can be explained by differences in surface area and cell volume. With spherostomatocytic transformation (0.5 mmol/L CP) membrane vacuoles were formed, which became detached from the cellular membrane towards the cell interior. The formation of intracellular membrane vacuoles reduced the membrane surface area and increased the cell volume by the volume of the vacuoles filled with suspending medium. Morphometric evaluation revealed that 3% of the cell interior of RBCs treated with 0.5 mmol/L CP was occupied by vacuoles, which alone can account for the 3% increase in MCV (Fig 5). The loss of surface area and the gain in volume because of such vacuole formation combined to cause the increase in sphericity, resulting in an increase in the sphericity index to 0.93.

Spheroechinocytes produced by 120 mmol/L SA also had an overall spherical appearance. But they were not spherocytic in a strict sense since the abundant number of little spicules lead to an increase of surface area by about 10%. This excess surface area was available for different types of

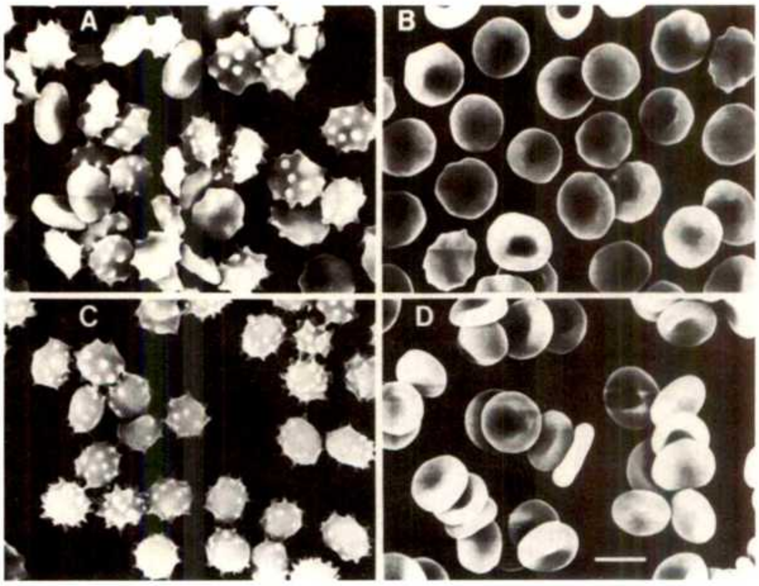

Fig 8. Scanning electron micrographs of 24-hour–depleted RBCs. (A) RBCs from whole blood incubated for 24 hours at 37 °C. (B) The same RBCs as in (A) suspended in Ringer's solution containing 0.5 g/dL bovine albumin. (C) RBCs of (A) suspended in Tris-buffered saline without albumin. (D) Fresh RBCs suspended in Tris-buffered saline for 20 minutes at 37 °C.

cellular deformation, eg, during osmotic swelling of the cells (Fig 7), RBC packing (Fig 6), and filtration. It has been reported that the membrane expansion produced by amphiphilic drugs that are incorporated into the membrane is several times greater than the pure volume of occupation within the membrane.[25] This has been explained on the basis of disordering and expansion of lipid regions, conformational changes, rearrangement of membrane proteins, and/or a change in membrane calcium content.[25] It is possible that these changes, in addition to the incorporation of SA into the membrane, contributed to the 10% membrane expansion found in our study. The volume of spheroechinocytes decreased, although it did not reach statistical significance. This is probably the result of the Gardos effect; salicylate increases the permeability for calcium, which activates calcium-sensitive potassium channels, leading to a loss of potassium and water from the RBC.[26]

Stomatocyte-echinocyte transformation has not been studied systematically with the RBC filtration test. It has been reported briefly that stomatocytes produced by chlorpromazine had a higher filtration pressure than normal discocytes.[27] Other methods that test the deformability of the whole cell have been used. Leblond[28] measured the pressure required to aspirate whole echinocytes into micropipettes with a diameter of 2.8 to 3.0 μm. This approach can be compared with the 2.6-μm pore filters of our study. It was found that echinocytes produced by lysolecithin and pH 8.5 required less pressure than discocytes. This finding is consistent with the lower filtration resistance following SA treatment found in our experiment. Leblond[28] also found that echinocytes produced by oleate required the same pressure as discocytes; echinocytes produced by ATP depletion required pressures ten times higher.

Another approach to the measurement of RBC deformability is to use a system without geometric constraints on individual RBCs as in narrow pores, eg, ektacytometry,[29] high speed centrifugation,[30] and the counterrotating rheoscope.[30] Using these methods it was found that stomatocytes produced by chlorpromazine are less deformable than discocytes[29,30] and that spherostomatocytes are undeformable,[29] which is in agreement with our results with filter pore sizes of 2.6 and 4.5 μm. Echinocytes III had a similar deformability in ektacytometry as discocytes, but spheroechinocytes were less deformable.[29] With high-speed centrifugation and the rheoscope, echinocytes were less deformable than discocytes.[30] The discrepancy between these findings and our results might be due to differences in methodology in the

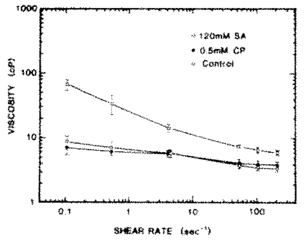

Fig 12. **Viscosity plotted against shear rate for suspensions of spheroechinocytes (120 mmol/L SA), spherostomatocytes (0.5 mmol/L CP), and discocytes (control). The hematocrit level was 45%. Values represent means ± SD, n = 4.**

three studies, eg, the use of different agents (lysolecithin in ref 29 and 2,4-dinitrophenol in ref 30) to produce echinocytes and the use of the highly viscous dextran solutions in ektacytometry[29] and the rheoscope.[30] Deformability tests with geometric constraints such as filtration through narrow pores might be more influenced by the cell geometry,[31] eg, the surface/volume ratio,[19] than those without geometric constraints (eg, deformation in a laminar flow field studied by ektacytometry and rheoscopy). The shear stresses applied in ektacytometry[29] and filtration[6] are similar (about 100 dyn/cm^2) and do not explain the differences. Spicules have been found to disappear at shear stresses above 10 to 15 dyne/cm^2.[30]

Although the changes in RBC deformability are explained by the changes in the relationship between surface area and volume, the other determinants of red blood cell deformability, ie, the cytoplasmic viscosity and the viscoelastic properties of the membrane, need be considered also. The corpuscular hemoglobin concentration, which determines primarily the cytoplasmic viscosity, did not change significantly in our study; in the case of spheroechinocytes, although there was a slight increase in the mean corpuscular hemoglobin concentration and an expected increase in cytoplasmic viscosity, the filtration resistance was reduced rather than increased. We are not aware of any study on the influence of chlorpromazine and salicylate on membrane deformability. It has been shown, however, that the filtration of RBCs through small pores is primarily affected by the cell geometry.[19] It is therefore likely that the increased sphericity of spherostomatocytes causes the increased filtration resistance and that direct effects of CP on the cell membrane are less important. Leblond[28] found that echinocytes produced by oleate or pH 8.5 required twice the negative pressure for a penetration of 1 μm into a micropipette with a diameter of 1.5 μm, indicating a reduced membrane deformability of echinocytes.

From this filtration study, which has a reasonable in vitro analogy of the flow through capillaries in vivo, it appears that echinocytes, at least those produced with SA, would pass more easily through the capillaries than normal discocytes. The question arises as to why the normal RBC is not echinocytic. Echinocytes have a rheologic disadvantage over discocytes, ie, suspensions of echinocytes have a higher viscosity (Fig 12). This is in agreement with an earlier communication by Meiselman[3] who attributed the increased viscosity to an enhanced cell-cell interaction or tangling of spicules. The increase in viscosity was more pronounced at low shear rates than at high shear rates. At high shear rates the surface of the echinocyte is gradually smoothened out by the high shear forces, as documented by direct observation in a rheoscope.[30] The high viscosity of echinocyte suspension would affect the bulk flow in larger blood vessels. It has recently been shown that echinocytes have also an impaired capacity of oxygen release.[32] The decrease in the rate of oxygen release was pronounced at low flow velocities, probably because of a stagnant unstirred layer around the echinocyte. At high flow velocities when the surface was shown to smooth out, the oxygen-releasing capacity returned toward normal.

Probably the best known cause of echinocytic transformation is ATP depletion. When red blood cells are metabolically depleted in vitro for 24 hours or longer, they become echinocytes.[7] The whole-cell deformability of those ATP-depleted echinocytes has been studied by several investigators, and there is general agreement that they are less deformable.[28,33] This is opposite to our results on echinocytes induced by salicylates. Therefore we performed experiments with 24-hour–depleted RBCs, and the results confirmed the earlier observations of a reduced deformability of these cells (Fig 9). The reason for the discrepancy between the two types of echinocytes may be explained by the fact that the sphericity index increased in ATP-depleted cells, whereas it decreased in salicylate-induced echinocytes. RBCs with the same shape may therefore have different surface area–to-volume relationships and consequently different deformabilities.

The increase in sphericity following ATP depletion was mainly the result of a cell swelling while the surface area remained unchanged (Fig 10); this could be explained by a breakdown of the sodium pump after ATP depletion. Meiselman found the discocyte-echinocyte transformation by ATP depletion to be isovolumic.[30] The difference may be due to the fact that he incubated washed RBCs in isotonic buffer solution, whereas we incubated unwashed RBCs in autologous plasma. Earlier communications support our result of an increased cell volume after metabolic depletion.[34,35] After incubations of >30 hours, a Gardos effect is observed, ie, losses of potassium and water from the RBCs.[8] The 24-hour depletion in this study did not affect the membrane surface area. It is known, however, that a longer depletion period during blood storage leads to a loss of membrane because of exovesiculation of the membrane.[36] This process would additionally increase sphericity and further decrease the filterability of these cells.

We conclude that echinocytic transformation can either be accompanied by an increase in sphericity, which leads to a decrease in deformability, or by a decrease in sphericity, which causes an increase in deformability. The sphericity and not the shape of a red cell appears to be the more important determinant of RBC passage through narrow channels. Stomatocytic transformation and ATP depletion cause an increase in sphericity and a decrease in red cell deformability. Salicylate-induced echinocytic transformation causes a reduction in sphericity and an increase in deformability. Red cell deformability determines not only the rheology of the circulating blood but also the life span of the individual red blood cell.[37] Our results suggest that the discocyte or shapes close to it represent an optimum shape for the in vivo situation. Stomatocytes with their decreased deformability in narrow channels are probably removed more rapidly by the spleen. The same holds true for echinocytes with increased sphericity as seen after metabolic depletion. Echinocytes with unchanged or even decreased sphericity are probably not removed by the spleen more rapidly, but they impair blood flow because of cell-cell interactions and hence increase blood viscosity.

These results may serve as a basis to study other hematologic disorders with an altered red blood cell shape, eg, hereditary elliptocytosis, spherocytosis, acanthocytosis, as well as acquired disorders with spiculed RBCs.[34]

Expression of Specific Granule Markers on the Cell Surface of Neutrophil Cytoplasts

By Pamela R. Petrequin, Robert F. Todd III, James E. Smolen, and Laurence A. Boxer

The widespread assumption that cytoplasts generated from human polymorphonuclear leukocytes (PMNs) are vesicles consisting solely of cytoplasm surrounded by plasma membrane and devoid of granule activity remains to be tested. PMN cytoplasts were prepared by centrifugation of intact cells on a Ficoll step gradient in the presence of cytochalasin B. Two granule membrane markers, Mol, a fluorometrically detectable antigen, and cytochrome b, both of which have been shown to translocate to the plasma membrane during granule release, were compared for their activity in cytoplasts and intact PMNs. We found that the amount of Mol detected on the plasma membrane of intact PMNs, as compared with other membrane markers (such as antigens LFA-1 and β_2m), increased 1.6-fold upon exposure of PMNs to Ficoll plus cytochalasin B prior to centrifugation. Another twofold increase in Mol expression occurred upon cytoplast preparation. Release of the granule enzymes, vitamin B_{12}-binding protein, and lysozyme were also followed and correlated well (r = .78 and .92) with the amount of Mol antigen present on the cell surface. Cytochrome b was also found to be higher (1.4-fold) on plasma membranes isolated from cytoplasts than on plasma membranes isolated from intact control cells. These results indicate that some fusion of granule membranes and plasma membranes occurred during treatment of PMNs with Ficoll plus cytochalasin b and during cytoplast preparation.

© 1986 by Grune & Stratton, Inc.

IT HAS NOT YET been demonstrated that cytoplasts generated from human polymorphonuclear leukocytes (PMNs) are vesicles consisting solely of cytoplasm surrounded by unmodified plasma membrane. The preparation of cytoplasts described by Roos et al[1] involves the centrifugation of cells on a Ficoll step gradient containing cytochalasin b at 34°. They showed that the isolated material consists of vesicles in which 41% of lactate dehydrogenase (LDH) and 33% of alkaline phosphatase activities were recovered.[1] Few granule contents were found in this fraction. Functionally, these vesicles were stimulatable by PMA to consume oxygen, and to produce superoxide and were able to phagocytize opsonized *Staphylococcus aureus*.[1] Others have found these particles to aggregate in response to *N*-formyl-methionyl-leucyl-phenylalanine (f-Met-Leu-Phe).[2]

Although Roos et al demonstrated that cytoplasts are deficient in soluble granule markers, their content of granule membrane markers has not been thoroughly examined. Two markers that are believed to be on granule membranes and have been shown to translocate to the plasma membrane after stimulation are Mol[3] and cytochrome b[4] Mol is a membrane antigen that is detectable on human monocytes, PMNs, and null cells.[5] It is believed to be an antigenic site on the C3bi receptor.[6] In immunoprecipitation studies[3] using anti-Mol monoclonal antibody, this antigen was localized to the fraction that has been shown to contain specific granules.[7] Translocation of Mol was demonstrated following stimulation with the calcium ionophore A23187, which caused a five- to tenfold increase in Mol expression on the plasma membrane accompanied by a significant amount of degranulation.[3]

Cytochrome b is another granule marker that has been shown to translocate to the plasma membrane of human PMNs following stimulation of the respiratory burst by soluble agents or opsonized particles.[4,7] There are some indications that cytochrome b is a component of the NADPH oxidase system because it is reduced after stimulation under anaerobic conditions.[8] However, attempts to directly correlate the translocation of cytochrome b activity with increases in oxidase activity upon stimulation have not been conclusive.[4,9,10]

The purpose of these experiments was to examine the claim that cytoplasts are truly free of granule activity. The approach used was to compare membranes from cytoplasts with those from intact control cells with respect to the aforementioned granule membrane markers. Our data indicate that degranulation occurred during cytoplast preparation and that plasma membranes of cytoplasts had significantly higher contents of Mol and cytochrome b than those of intact cells.

MATERIALS AND METHODS

Chemicals Ionophore A23187 was purchased from Calbiochem-Behring Corp, La Jolla, Calif. Ficoll 70 and Percoll were purchased from Pharmacia Fine Chemicals, Uppsala, Sweden. (^{57}Co)-vitamin B_{12} and (γ-^{32}P)-ATP were purchased from Amersham Corp, Arlington Heights, Ill. All other reagents were purchased from Sigma Chemical Co, St Louis, unless otherwise stated A23187 and cytochalasin B were dissolved in dimethyl sulfoxide and then added to aqueous solutions with vigorous mixing.

Monoclonal antibodies. Mouse ascites containing monoclonal antibodies specific for LFA-1[11] (IgG1 subclass, a gift from Dr Hergen Spits, Amsterdam, Holland), Mol[5] (IgG2a subclass), β_2m[12] (IgG2b subclass, a gift of Dr Lee Nader, Boston), and Ia[13] (IgG2a subclass) were used in indirect immunofluorescence analysis.

Preparation of cells Suspensions of PMNs were prepared from heparinized (10 U/mL) venous blood from healthy adult donors. Standard techniques of Hypaque-Ficoll gradients[14] followed by dextran sedimentation and hypotonic lysis of erythrocytes provided a PMN suspension that was 98% pure. Neutrophils were washed in phosphate buffered saline (PBS) (138 mmol/L NaCl, 2.7 mmol/L

KCl, 8.1 mmol/L Na_2HPO_4, and 1.5 mmol/L KH_2PO_4, pH 7.4) before use.

Cytoplast preparation. Cytoplasts were prepared according to Roos et al.[1] In brief, washed PMNs were resuspended in incubation medium (PBS, pH 7.4, with 0.6 mmol/L $CaCl_2$, 1.0 mmol/L $MgCl_2$, 5.5 mmol/L glucose, and 0.5% bovine serum albumin [BSA]) and incubated for five minutes at 37 °C. The suspension was centrifuged at 700 g at room temperature for six minutes. The cell pellets were resuspended in 12.5% Ficoll with 20 µmol/L cytochalasin b, incubated for five minutes at 37 °C, and then layered on a Ficoll step gradient (16%/25%: 5.5 mL of each containing 20 µmol/L cytochalasin b). This gradient was centrifuged at 81,000 g at 34 °C for 30 minutes in a Beckman SW 28.1 rotor in a Beckman L65-B ultracentrifuge (Beckman Instruments, Inc, Fullerton, Calif). The materials at the interfaces were collected and then washed twice in PBS, pH 7.4, with 10 mmol/L $CaCl_2$ and 10 mmol/L $MgCl_2$.

Plasma membrane preparation. Approximately 2.5 × 10^8 washed PMN were resuspended in 12 mL of relaxation buffer (100 mmol/L KCl, 3 mmol/L NaCl, 3.5 mmol/L $MgCl_2$, and 10 mmol/L piperazine-*N*, *N*¹-bis(2-ethanesalfonic acid), pH 7.3) and pressurized under N_2 for 20 minutes with stirring in a nitrogen bomb[15] The cavitate was collected dropwise into ethylene glycol tetraacetic acid for a final concentration of 1 mmol/L For the isolation of plasma membranes, the procedure of Borregaard et al[7] was followed with minor changes. Fourteen milliliters of a 1.044-g/mL Percoll solution were added to a 50-mL polycarbonate tube (Beckman, Irvine, Calif), and 14 mL of the 1.11-g/mL Percoll were layered using a spinal needle The cavitated sample, 8.0 to 10.0 mL, was layered on top and centrifuged at 4° for 17 minutes at 20,000 rpm in a Beckman JA-20 rotor using a Beckman J2-21M centrifuge The bands of material at the two interfaces, γ and β, and the pellet at the bottom, α, were collected. Percoll was removed by centrifugation at 100,000 g for 105 minutes at 4 °C in a Beckman SW 41 rotor. Material lying on top of the Percoll pellet was collected with a Pasteur pipette.

Enzyme marker analysis. Alkaline phosphatase was assayed according to DeChatelet and Cooper,[16] with 10 mmol/L *p*-nitrophenol phosphate (Sigma) in a 50 mmol/L glycine buffer, pH 10, with 10 mmol/L $MgCl_2$. The enzyme activity was calculated using the extinction coefficient for *p*-nitrophenol (18.6/L · $mmol^{-1}$ · cm^{-1}).[17]

Vitamin B_{12}–binding protein was measured by a modification of the method of Gottlieb et al.[18] Sixteen picograms of (^{57}Co)–vitamin B_{12} in 0.6 mL of saline with 200 pg of carrier vitamin B_{12} was added to the protein sample in 1.0 mL of saline for a final specific activity of 90 cpm/pg The reaction was run for 30 minutes at room temperature after which 1.0 mL of 2.5% charcoal, 0.5% vitamin B_{12}–deficient BSA (Sigma) in 0.9% NaCl was added to stop the reaction. Samples were centrifuged for ten minutes at 800 g at room temperature, and 1.0 mL aliquots of the supernatants were collected and counted in a Tractor Analytic Model 1190 (TM Analytic, Elk Grove, Ill) gamma counter to determine the amount of bound (^{57}Co)-B_{12}

LDH was measured as described by Wacker et al[19] Lysozyme was measured turbidometrically[20] using egg white lysozyme (Sigma) as a standard. β-Glucuronidase was assayed using phenolphthalein β-D-glucuronide as a substrate.[21] Activity was calculated using an extinction coefficient of 33 L · $mmol^{-1}$ · cm^{-1} at 540 nm.[22] Mg–adenosine triphosphatase (Mg-ATPase) was assayed as previously described.[23] Myeloperoxidase was assayed according to the procedure of Bretz and Baggiolini.[24] Protein was measured according to the Bradford procedure.[25]

Cytochrome b determination. Cytochrome b was assayed by performing difference spectra from 600 to 400 nm on samples sonicated in PBS[26] Scans of samples reduced in sodium dithionite minus background scans of oxidized sample produced characteristic cytochrome b peaks at 559 nm and 428 nm Although the 559-nm peak was more characteristic of cytochrome b activity, the 428-nm peak was larger and a more sensitive measure. Cytochrome b was quantitated using an extinction coefficient of 106 L · $mmol^{-1}$ · cm^{-1} for the 428-nm peak.[9]

Immunofluorescent analysis of membrane antigens Indirect immunofluorescence of Mol, LFA-1, and β2-microglobulin was measured by cytometry as described by Todd et al.[3] The channel number (log scale) measuring the mean fluorescence intensity of 5,000 cells that had been exposed to either an experimental or a negative control antibody (anti-Ia) and then to a fluorescein-conjugated goat antimouse immunoglobulin was determined. Logarithmic channel numbers were converted to linear values[27] and the specific mean fluorescence intensity for cells stained by experimental antibodies was calculated by subtracting the mean channel number of cells exposed to the negative control antibody from that of cells stained by the experimental antibodies

RESULTS

Preparation of cytoplasts. To examine the claim that cytoplasts are truly free of granule activity,[1] a comparison of cytoplast membranes with those from intact cells for the appearance of two granule membrane markers was performed. It may be that during cytoplast preparation degranulation occurs and results in the fusion of granule membranes with the plasma membrane. Cytoplasts were prepared according to the method of Roos et al[1] using a Ficoll step gradient containing cytochalasin B. The recoveries of the various soluble enzymes in the isolated fractions are shown in Table 1 The results are similar to those of Roos et al,[1] with the largest amounts of LDH (39%) and protein (42%) being recovered in the cytoplast fractions (band 1). Examination of the material at this position using light microscopy showed only vesicles without nuclei. Since cytoplasts are believed to consist of only cytoplasm surrounded by plasma membrane,[1] the activities of soluble granule enzymes were compared to the cytoplasmic marker LDH as an indication of the relative purity of the cytoplast fraction (Table 2). Comparing the cytoplast fraction to intact PMNs, decreases in all enzyme activities were observed. The largest decreases were in granule constituents, vitamin B_{12} binding protein, β-glucuronidase, myeloperoxidase, and lysozyme, as was expected since cytoplasts have been shown to be deficient in these

organelles.[1] Alkaline phosphatase activity with respect to LDH did not change.

Degranulation and Mol expression during cytoplast preparation. Several steps during cytoplast preparation such as warming to 37° and treatment with cytochalasin B could cause degranulation and translocation of granule membrane markers. To determine whether degranulation occurs during the early stages of cytoplast preparation, release of granule contents and surface Mol antigen expression were measured. Figure 1 shows a comparison of the release of two granule constituents, lysozyme and vitamin B_{12}–binding protein, and Mol expression of intact cells at each step of cell treatment, then followed by stimulation with A23187. It can be seen that there was an increase in both enzyme release and Mol expression at every condition but the fifth (incubation for an additional 30 minutes in Ficoll with cytochalasin B). During the early preincubation steps of warming the PMNs for five minutes at 37° in Ficoll plus cytochalasin B before layering on the gradients, the largest increase in Mol expression and enzyme release occurred. Subsequent incubation of the PMNs for 30 minutes in Ficoll and cytochalasin B, which would be comparable to the conditions intact cells would be under when they were on the gradient except without centrifugation, did not result in an additional increase in Mol expression However, treatment with A23187 caused a significant increase in Mol expression and enzyme release, indicating that further degranulation was possible.

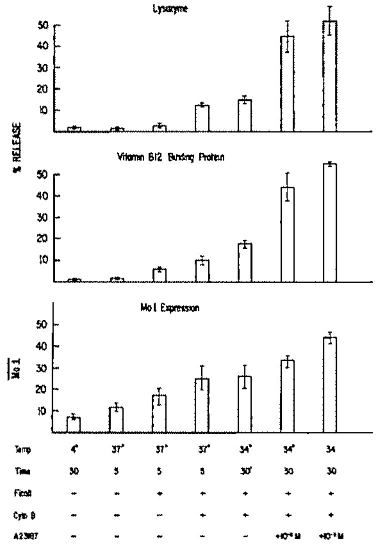

Fig 1. Mol expression and specific granule release from intact PMNs during sequential steps leading up to cytoplast preparation and then followed by activation of intact PMNs with ionophore A23187. Separate aliquots of PMN (5 × 10^7/mL) from the same donor were put on ice or incubated for five minutes at 37 °C, washed, and then treated under the indicated conditions. Specific intensity mean fluorescence arbitrary units (±SE) with anti-Mol antibody and release of enzymes into the cell supernatant (±SE) were measured in four experiments. Cells stimulated with A23187 were incubated for 30 minutes with 12.5% Ficoll plus 20 μmol/L cytochalasin B at 34 °C before exposure to A23187 for ten minutes at 37 °C. The release of LDH was <2% without ionophore and <7% in the presence of ionophore.

Since both Mol and specific granule release increased during cytoplast preparation, the correlation between these two responses was calculated. For Mol expression and vitamin B_{12} binding protein release and for Mol and lysozyme release, the correlation coefficients were .78 and .92 respectively These have a P value of less than .001 for $n = 19$ and, thus, are highly significant. As anticipated, the release of the two granule constituents vitamin B_{12}–binding protein and lysozyme correlated well with each other ($r = .89$, $P < .001$).

Expression of Mol and plasma membrane markers. Although the mean Mol expression increased during the initial stages of cytoplast preparation, it was important to see how Mol behaved in relation to known plasma membrane markers during these manipulations and after cytoplasts had been generated The two plasma membrane markers that were chosen, LFA-1 and β_2m, have been shown to remain constant even after stimulation with f-Met-Leu-Phe.[28,29] Table 3 shows the ratio of Mol to two plasma membrane markers, β_2m and LFA-1, for cells at 4°, after Ficoll plus cytochalasin B treatment and after cytoplast preparation. A comparison of the ratios of Mol to LFA-1 for PMNs incubated in Ficoll with cytochalasin B and for cytoplasts showed that there was an increase (1.9-fold) in the appearance of Mol after cytoplast preparation. Cells left at 4° had a much lower Mol/β_2m ratio than those exposed to Ficoll plus cytochalasin B at 37° (Table 3). This observation confirmed the results shown in Fig 1, namely, that treatment with Ficoll and cytochalasin B caused a significant increase in Mol expression. In close agreement with the Mol/LFA-1 result, the ratio of Mol to β_2m was significantly higher (1.6-fold) for cytoplasts than for PMNs treated with Ficoll plus cytochalasin B. The mean fluorescence intensities for LFA-1 and β_2m on a per-particle basis did not change under any condition (data not shown). Stimulation by A23187 (10^{-6} mol/L) of PMNs treated with Ficoll plus cytochalasin B increased the amount of Mol, indicating that further stores of Mol were available The

§$P < .01$ (using paired statistics) when compared to Ficoll + cytochalasin B–treated cells without A23187.

ratio for cytoplasts did not change after stimulation with A23187, which is consistent with the notion that the cytoplasts were deficient in granules.

Analysis of cytochrome b in plasma membrane preparations. Another specific granule marker, cytochrome b, was followed during cytoplast preparation as a monitor of degranulation. Since we wished to measure the activity of cytochrome b that had translocated to the plasma membrane and not that which was still present in the granules, analysis of cytochrome b was performed on isolated plasma membrane fractions. Table 4 shows a comparison of the specific activities of cytochrome b and plasma membrane markers in untreated PMNs, PMNs treated with Ficoll plus cytochalasin B, and cytoplasts. There was a significant increase in the specific activity of cytochrome b in plasma membranes from cells that had been treated with Ficoll plus cytochalasin B as well as those from cytoplast preparations. To determine whether Ficoll plus cytochalasin B increased the amount of cytochrome b in cells, the total cytochrome b content of intact cells with and without this treatment was measured; no difference in cytochrome b content was found (data not shown).

The activities of alkaline phosphatase and Mg-ATPase were also measured (Table 4) so that cytochrome b could be compared to two membrane markers in a manner analogous to the comparison of Mol to LFA-1 and to β_2m (Table 3). This comparison was crucial since the relative protein content of plasma membranes isolated from PMNs appeared to decrease after treatment with Ficoll plus cytochalasin B and, again, after cytoplast preparation. The activity of alkaline phosphatase also appeared to decrease, making the usefulness of this marker questionable. Another plasma membrane marker, Mg-ATPase, did not change during these treatments. Table 5 shows the ratios of cytochrome b content relative to the two plasma membrane marker activities. As predicted from the earlier results with Mol expression, the ratio of cytochrome b to alkaline phosphatase was significantly higher in plasma membranes from cells treated with Ficoll plus cytochalasin B than those from untreated PMN. A similar significant increase was found for the cytochrome b/Mg-ATPase ratio. The preparation of cytoplasts further increased the ratio of cytochrome b to alkaline phosphatase; the ratio of cytochrome b to Mg-ATPase was not altered by this final step.

Table 4. Enzyme Activity in Plasma Membrane Preparations Obtained at Different Stages of Cytoplast Preparation

	Specific Activity*		
Marker	PMN	PMN Ficoll + CB†	Cytoplasts

DISCUSSION

The question of whether cytoplasts are devoid of all granule activities has been considered. Our preparation of cytoplasts was similar to that of Roos et al[1] in recovery of protein and marker enzyme activities. Our yield of cytoplast material was slightly lower than that reported by the latter investigators; recovery of LDH was 38% instead of 48% and that of alkaline phosphatase was 18% instead of 33%. In spite

of this, our cytoplast preparation was similar in having greatly reduced amounts of soluble granule enzymes.

Our studies indicate that degranulation and translocation of two granule membrane markers occurred during cytoplast preparation. In particular, we showed that the series of manipulations involved in cytoplast preparation increased Mol expression and the release of lysozyme and vitamin B_{12}–binding protein in a stepwise fashion. The good correlation between the release of the two specific granule constituents and Mol expression provided further evidence that Mol was a marker of degranulation. Significant increases in the ratio of Mol/β_2m (3.3-fold, Table 3) as well as that of cytochrome b/Mg-ATPase in the cell membrane (2.7-fold, Table 5) occurred upon incubation of PMNs with Ficoll plus 20 μmol/L cytochalasin B. The preparation of cytoplasts further increased the appearance of Mol on the cell surface (1.6-fold, Table 3) and the specific activity of cytochrome b in the plasma membrane (1.4-fold, Table 4). Therefore, our data suggest that cytoplast membranes contain significantly higher amounts of granule membrane activity than those of untreated cells.

Degranulation was shown to occur during the Ficoll and cytochalasin B pretreatment of cells for cytoplast preparation. The demonstration that Mol expression increased in a fashion similar to the release of lysozyme and vitamin B_{12}–binding protein is an important finding. Although degranulation had previously been shown to occur under conditions in which Mol expression is increased,[3] this is the first report of a good correlation between Mol expression and enzyme release. This is not to be expected since Mol is a surface antigen that, unlike granule enzymes, has a low but significant level of expression on unstimulated cells (Fig 1). It should be noted that this good correlation does not necessarily support the hypothesis that Mol is located in specific granules.

The largest increase in Mol expression as compared to PMNs left at 4° occurred during the five-minute incubation of cells with Ficoll and cytochalasin B at 37°. The ability of cytochalasin B to enhance PMN responses is well documented.[10,30–33] Cytochalasin B is thought to enhance stimulation by increasing influxes of Ca^{+2} and Na^{+} ions.[32] There is one report showing that cytochalasin B alone causes the stimulation of oxidase activity.[33] Our data also indicate that cytochalasin B can cause a significant amount of degranulation in the presence of Ficoll.

Stimulation with the calcium ionophore A23187 in the presence of cytochalasin B increased the amount of Mol expressed and the amount of granule enzymes released from intact cells, but not from cytoplasts. The inability of A23187 to increase Mol in cytoplasts indicates that internal stores of Mol were not present in cytoplasts. This finding is in agreement with that of Lutter et al who showed that stimulation with PMA increased the content of cytochrome b in the membranes of intact cells but not those of cytoplasts.[9]

It is noteworthy that stimulation with A23187 did not increase Mol by the same proportion as it did the release of lysozyme and vitamin B_{12}–binding protein. This could to some extent be attributed to higher baseline levels of Mol, which, as already discussed, could be increased by low-level degranulation during the cell's history. The higher stimulated levels of lysozyme as compared to Mol might be explained by the contributions of enzyme from azurophil granules. That lysozyme might also be released from this other source was suggested by the release of β-glucuronidase, an azurophil granule enzyme, after stimulation by A23187 (data not shown).

The comparison of Mol to two membrane markers, LFA-1 and β_2m, demonstrated that the preparation of cytoplasts caused further translocation of Mol to the cell surface. The amounts of the two plasma membrane markers have been shown not to change after exposure to degranulating stimuli,[28,29] making them suitable steady-state determinants for comparison to Mol. The higher ratio of Mol/β_2m for cells treated with Ficoll plus cytochalasin B as compared to untreated PMNs (Table 3) is consistent with the data in Fig 1 correlating the mean fluorescence of Mol to enzyme release. The relationship between Mol and the plasma membrane markers LFA-1 and β_2m was analogous to the positive correlation between the specific activity of cytochrome b with respect to Mg-ATPase (which was also found to increase under similar conditions).

To determine whether another specific granule marker, cytochrome b, also translocated to the cell membrane during cytoplast preparation, plasma membrane fractions were prepared. These fractions were enriched 12-fold in alkaline phosphatase and Mg-ATPase activities (data not shown). The plasma membrane fractions from cytoplast gradients had a smaller increase (sixfold) in specific activity, presumably because with most of the granules eliminated the plasma membrane protein could make a larger contribution to the total. As with Mol expression, the largest increase (twofold) in the specific activity of cytochrome b occurred when the cells were incubated in the presence of Ficoll with cytochalasin B; cytoplast preparation further increased its specific activity (1.4-fold). When the cytochrome b content was compared to Mg-ATPase activity, a significant increase in the ratio occurred upon incubation of cells in Ficoll with cytochalasin B. The comparison of cytochrome b to alkaline phosphatase activity magnified these differences, presumably because of the loss of enzyme activity with each treatment.

Our results differ somewhat from some other reports measuring cytochrome b content in cytoplasts as compared to intact cells.[9,10] Some investigators used untreated, intact PMNs as controls, whereas we examined both these as well as cells treated with Ficoll plus cytochalasin B. Analyzing the specific activity of cytochrome b with respect to protein, Ohno et al[10] found no difference between the plasma membranes of intact cells and those of cytoplasts. In contrast, we demonstrated significant differences in cytochrome b activity among plasma membrane preparations from untreated cells, from cells treated with Ficoll plus cytochalasin B, and from cytoplasts. Since granule membranes have a density similar to plasma membranes,[7] there may be a problem of contamination of plasma membrane fractions. In another report, Lutter et al compared cytochrome b to alkaline phosphatase activity and found that plasma membranes of intact cells had a ratio twice as high as that of cytoplast membranes.[9] Our results showed the opposite, with plasma membranes of cytoplasts having a higher cytochrome b/alkaline phosphatase ratio than those of either PMNs treated with Ficoll plus cytochalasin B or untreated cells. Contributing to these results are the large changes in alkaline phosphatase specific activity between the different fractions (Table 4). This could be due to differences in protein composition of the plasma membrane induced by the various treatments. However, this decrease in specific activity during cytoplast preparations was not seen with Mg-ATPase, indicating that the two plasma membrane markers were not distributing identically. Nonetheless, no matter how cytochrome b specific activity was calculated (eg, with respect to protein, alkaline phosphatase, or Mg-ATPase), a significant increase in activity was found after treatment with Ficoll plus cytochalasin B. Furthermore, this is in agreement with the results of Mol expression (Table 3). Thus, these data strongly suggest enrichment of granule membrane components in the plasma membrane during the steps of cytoplast preparation.

The intracellular sources of Mol and cytochrome b have not been determined. Mol has been shown to have an intracellular pool that migrates to the plasma membrane after activation of human PMNs.[3,34] One source for Mol that has been implicated by some recent experiments is the tertiary granule, a gelatinase-containing granule originally described by Dewald et al.[35] We have shown that by using stimuli under conditions in which specific and azurophilic granules are not released, both Mol expression and gelatinase release occur.[36] We infer from these results that one intracellular source of Mol is the tertiary granule. One source of evidence locating cytochrome b to the specific granule comes from studies with a specific granule–deficient patient.[37] The PMNs from this patient, which lack specific granules, do not contain cytochrome b in any granule fraction, implying that the specific granule is the source of cytochrome b. On the other hand, PMNs from this patient are capable of up-regulating Mol (unpublished data), indicating that other sources for Mol exist besides the specific granule. Another possible intracellular membrane source for these markers, which has not been excluded by these experiments, may be the receptor recycling system, receptosomes.[38]

In conclusion, degranulation occurred during the various stages of PMN cytoplast preparation as indicated by enzyme release and the translocation of granule membrane markers to the PMN plasma membrane. The increases in Mol expression and cytochrome b activity on the cell membrane upon incubation in Ficoll plus cytochalasin B and during cytoplast preparation indicate that cytoplasts are not devoid of granule membrane content.

Evaluation by Quantitative Acid Elution and Radioimmunoassay of Multiple Classes of Immunoglobulins and Serum Albumin Associated With Platelets in Idiopathic Thrombocytopenic Purpura

By Adair J. Hotchkiss, Cindy A. Leissinger, Mark E. Smith, James V. Jordan, Carol A. Kautz, and N. Raphael Shulman

Immunoglobulins (Igs) and serum albumin were eluted from normal platelets and platelets from patients with idiopathic thrombocytopenic purpura (ITP) with a quantitative acid elution procedure followed by solid-phase radioimmunoassay (SPRIA). Acid elution was shown to release a reproducible fraction of platelet-associated Igs, and the amounts released per platelet were independent of the platelet concentration over a wide range of concentrations. This procedure is suitable for sensitive, reproducible, and specific quantitation of large numbers of samples. Washed platelets from 13 normal donors contained the following components (expressed in femtograms per platelet, mean ± 2 SEM): IgG, 1.40 ± 0.26; IgA, 0.72 ± 0.36; IgM 0.078 ± 0.036; albumin 7.7 ± 1.5. Immunoglobulins and albumin eluted from the platelets of ten ITP patients (two in remission), expressed as femtograms per platelet, mean (range), were: IgG 104 (0.3 to 750); IgA 90 (0.9 to 715); IgM 162 (1.2 to 1,300); and albumin 34 (6.8 to 199). All platelet-associated Igs from thrombocytopenic ITP patients were found to be elevated twofold to 2,300-fold with one Ig class occasionally elevated 50-fold to 100-fold higher than the others. A similar group of ten thrombocytopenic ITP patients was found to have twofold to 26-fold elevations of platelet-associated albumin. This demonstration of increases in multiple classes of Igs as well as serum albumin associated with platelets from ITP patients suggests that some nonimmune process may be contributing to the phenomenon of increased platelet-associated proteins in ITP.

© 1986 by Grune & Stratton, Inc.

ITP FACTOR capable of inducing thrombocytopenia by passive transfer has been shown to be present in the purified IgG fraction from the plasma of patients with idiopathic thrombocytopenic purpura (ITP).[1,2] Measurement of platelet-associated IgG (PAIgG) has become a frequently used diagnostic test in ITP. Numerous reports have shown that PAIgG is elevated in most cases of ITP and that the degree of elevation is inversely related to the platelet count (for review, see ref. 3). Recent reports, however, have described some ITP patients who have elevated platelet-associated IgM[4-9]; other studies have shown increased platelet-associated IgA as well.[9-12] Finally, elevations of platelet-associated C3[9,13,25] and C4[9] in thrombocytopenic ITP patients have been reported.

We have found that washed platelets from normal individuals have measurable levels of both IgA and IgM in addition to IgG; furthermore, normal platelets also possess measurable quantities of albumin. Our findings indicate that when PAIgG is elevated in ITP, platelet-associated IgM, IgA, and albumin are also elevated in most instances. These results suggest that the increased levels of immunoglobulins in platelet preparations from ITP patients may be due partly to mechanisms unrelated to antigen–antibody binding; the same mechanisms may also account for the attachment of albumin and possibly other serum proteins.

MATERIALS AND METHODS

Platelet preparation. Blood was drawn by the two-syringe technique and immediately added to a 10% solution of dipotassium EDTA 17 µl/mL of whole blood. The platelet-rich plasma (PRP) was made by centrifuging whole blood at 400 g for four minutes. PRP was centrifuged at 1,500 g for 15 minutes, and the platelet pellet was suspended in 1.0% ammonium oxalate for ten minutes. After being pelleted, the platelets were washed three times in 0.15 mol/L of NaCl (saline) and suspended in saline. Platelets were either eluted immediately or were stored at 4 °C with 0.02% sodium azide.

Quantitative acid elution. All subsequent steps were carried out at 4 °C unless otherwise noted. The general elution procedure was to suspend the platelets in unbuffered saline and add some volume of acid buffer with bovine serum albumin (BSA) (Miles, Naperville, Ill, Fraction V) to achieve a final acid concentration of ~50 mmol/L and a final BSA concentration of 0.5%; for example, a 200-µl aliquot of the final saline suspension containing from 0.1 to 1 × 10^8 platelets was acidified by the addition of 100 µL of 150 mmol/L of H_3PO_4, 100 mmol/L of NaCl, 1.5% BSA, pH 2.8. Acetic acid (150 mmol/L), titrated to pH 2.8 with HCl, can be used in place of H_3PO_4 with identical results. After ten minutes, the suspension was centrifuged in a Beckman Microfuge 12 at maximum speed (~10,000 g) for two minutes. A predetermined amount of 2.5 mol/L of Tris base was added to 250 µL of the supernatant to raise the pH to 8.0 to 8.1, and sodium azide was added to 0.02%. This platelet extract could be stored at 4 °C for periods up to two months without adsorption of the Igs to polyethylene tubes or loss of immunologic reactivity.

Ig quantitation. Igs were quantitated by a solid-phase radioimmunoassay (SPRIA) technique using flexible polyvinyl chloride plates (Dynatech, Alexandria, Va) coated with heavy chain-specific, affinity-purified, goat anti-human IgG, IgA, or IgM, (Kirkegaard & Perry Labs, Rockville, Md). The plates were coated by adding 80 µl of 10 mmol/L of $NaPO_4$, pH 8.0, with 0.02% NaN_3 to each well of the 96-well microtiter plate followed by 20 µL per well of the heavy chain-specific antibody, at 25 ng/µL, in the same phosphate buffer. To avoid adsorption of the anti-Ig to the test tube, all procedures were done at 4 °C, and only enough of the antibody was diluted from a 1 mg/mL solution in 150 mmol/L of NaCl, 10 mmol/L PO_4, pH 7.4 (PBS) for preparation of one plate. The plates were incubated overnight at 4 °C in a humidified airtight container and were then washed three times by flooding with phosphate-buffered saline (PBS), 0.5% BSA, 0.02% NaN_3 (BSA/PBS) and incubated with BSA/PBS for at least 30 minutes prior to use to block residual protein binding sites. Usually, 10 to 12 plates were prepared at one time; these could be stored full of the final wash solution at 4 °C in a humidified chamber for as long as three months.

The same heavy chain-specific antibody used to coat the plates

was used as the labeled second antibody; ^{125}I was coupled to these antibodies by the chloramine-T method. Na^{125}I [16.6 mCi/μg iodine (Amersham, Arlington Heights, Ill, #IMS300)] was added to the antibody in the ratio of 2 μCi/mg of protein in 100 mmol/L (final) of phosphate buffer, pH 7.5. The reaction was initiated by the addition of chloramine-T (0 5 μg/μg of protein), incubated with gentle mixing for 90 seconds and terminated by the addition of a saturated tyrosine solution (0.5 mL/μg of protein). After 60 seconds, the mixture was applied to a Dowex AG1-X8 (200 to 400 mesh) column (7 × 25mm) which was preequilibrated with borate (345 mmol/L)-buffered BSA (0.1%) solution (BBSA, pH 8.55); the column was washed with successive 500-μL aliquots of BBSA. The major portion of radioactivity eluted in the second and third column fractions. More than 95% of the radioactivity in this preparation was eluted in the void volume of a Sephadex G25 column (Pharmacia PG-10) Therefore, the eluate from the Dowex column was used without further purification.

Between 10 and 40 μL of the platelet acid eluates were added to antibody-coated microtiter wells that had been sucked dry of the BSA/PBS solution and filled with 100 μL of radioimmunoassay (RIA) buffer (100 mmol/L of Tris, pH 8.1, 50 mmol/L of NaCl, 0.5% BSA, 0.02% NaN_3). Chromatographically purified IgG (Cappel), secretory IgA (Calbiochem, Malvern, Pa), or IgM (Calbiochem, San Diego, Calif) standards from 0.1 to 500 ng per well, in the same volume as the eluates, were added to other wells for the standard curves, in a buffer that reproduced the neutralized acid eluate. The plates were either incubated at room temperature for two hours or overnight at 4 °C. The plate was then placed on an ice bed for at least ten min, the unbound material was thrown off, and the plate was washed three times by flooding with ice-cold BSA/PBS. The wells were aspirated dry, and 100 μL of ^{125}I-labeled goat anti-human Ig (50,000 cpm per well) in RIA buffer was added to each well and incubated for 90 minutes at 21 °C. The plates were then chilled on ice for ten minutes, sucked dry, and washed three times with 160 μL of cold BSA/PBS. The plates were dried, and individual wells were cut out and counted in a gamma counter. Maximum binding was achieved with 500 ng per well of antigen (generally between 9,000 cpm and 15,000 cpm) The Ig blank (usually <200 cpm) was subtracted from all data.

The standard curves were graphed as the logit (+5) of cpm *v* the negative log of Ig which allows a least-squares linear regression to be fit to the data (Fig 1, insert); reliable data were obtained in the range of 0.5 to 30 ng of Ig per well.

Serum albumin quantitation. Human serum albumin (HSA) was quantitated by a solid-phase competitive binding assay. One hundred microliters of diluted goat antiserum to HSA (Cappel) was added to the microtiter well (500 μg of protein per well, whole serum) and the plates were incubated, washed, and blocked as with the Ig assays. Crystalline HSA (Miles, Naperville, Ill) was labeled, as described above, with ^{125}I, 4 μCi/μg of protein; the labeled serum albumin was mixed with the platelet eluate or an albumin standard, and 100 μL of the mixture containing 60,000 cpm was added to the antiserum-coated wells, incubated for two hours at 21 °C or overnight at 4 °C, washed three times as with the Ig assays, dried, and counted. The maximum binding was typically 10,000 cpm, which could be maximally displaced by 500 ng of HSA per well; the useful range of the assay was typically from 2 to 200 ng per well This assay system could therefore measure platelet-associated albumin (PAA) given as little as 5 mL of whole blood from a normal donor or 40 mL of whole blood from a severely thrombocytopenic patient (a platelet count of 10,000/μL).

Patients with ITP All patients had thrombocytopenia with an increased number of megakaryocytes in the bone marrow and no associated abnormality or disease process that might account for thrombocytopenia. The patients' tests for antinuclear antibodies and rheumatoid factor were all negative. The one pediatric patient studied had acute ITP, and all others had chronic ITP Platelet counts of the patients are tabulated in the text.

RESULTS

Sensitivity of these assays was of primary importance in evaluating samples with scarce material from severely thrombocytopenic patients. Figure 1 shows that this solid-phase sandwich system is accurate to <1ng/40 μL. When necessary, the sensitivity of these assays could be increased at least tenfold by using a smaller volume of the diluting RIA buffer and/or by concentrating the platelets in the acid elution procedure. Dilution of sample in the RIA buffer was performed to prevent minor pH variations between empirically neutralized samples. The use of polyclonal antibodies gives a wide standard curve which spans nearly two logs of concentration. The logit transformation of the standard curve, plotted by linear regression analysis, is convenient for measuring unknowns.

The ability of the assay system to distinguish between the classes of immunoglobulin was particularly critical for this study. The heavy chain-specific antibodies show insignificant cross-reactivity with other classes for the purposes of this study (Fig 1). The three other combinations for testing

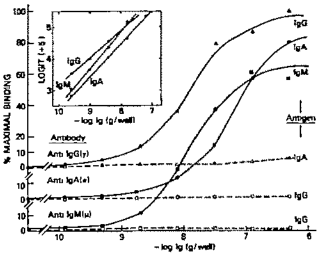

Fig 1. Binding curves for IgG on anti-IgG (▲——▲), IgA on anti-IgG (△—△), IgA on anti-IgA (●——●), IgG on anti-IgA (O—O), IgM on anti-IgM (■——■), and IgG on anti-IgM (□—□). Inset: Logit was defined as $\text{Log}_{10}P/(1 - P)$ where P equals the fraction of maximal specific binding. Typical logit transformation standard curves for IgG (△), IgA (O), and IgM (□), run in duplicate, are shown. The average coefficient of variation was 0.36 ± 0.12 for (logit +5) values between 3 and 5.

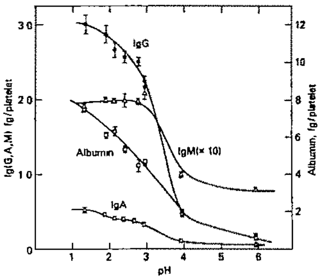

Fig 2. pH-dependent elution of gamma globulins and albumin: IgG (●), IgA (O), IgM (△), and albumin (□) eluted per platelet. Values are shown as mean ± SEM of duplicate assays on pooled platelets of three normal individuals. Note that IgM values are multiplied by 10 in this plot. The acid buffer was 50 mmol/L of PO_4, 50 mmol/L of acetic acid, 50 mmol/L NaCl, 0.5% bovine serum albumin (BSA), and 0.02% NaN_3 for each point; pH was measured at room temperature.

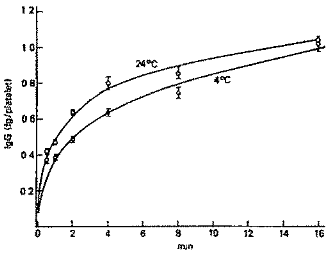

Fig 3. Time course of IgG elution at pH 2.65; 2 × 10^8 platelets in 200 µL saline were acidified with 100 µL of acid buffer.

cross-reactivity (anti-IgG with IgM, anti-IgA with IgM, and anti-IgM with IgA) show similar results.

The effect of pH on the elution of various platelet-associated proteins is shown in Fig 2. IgG and IgM show a sharp increase in elution below pH 4, IgA shows a more gradual increase, and albumin shows a progressive elution over a wide range of decreasing pH values. A pH between 2.7 and 2.8 was suitable for eluting a high percentage of Igs at minimal risk of denaturation Treatment of IgG, IgM, IgA, and HSA standard proteins under conditions of acid elution produced no detectable change of antigenicity as judged by comparing assays before and after treatment. Moreover, when 5 to 240 ng/µL of IgG, IgM, IgA, or HSA was added to 2 × 10^8 platelets in 200 µL before acid elution was performed, essentially 100% of the added proteins was recovered, as measured by the solid-phase RIA (SPRIA) technique. Thus, acid treatment per se and the presence of soluble platelet materials released by acid treatment did not interfere with the specificity or sensitivity of the SPRIA.

The time course of elution of IgG from washed platelets is shown in Fig 3. The amount of IgG eluted approached an asymptotic value after eight minutes, and the rate of elution was only slightly increased at 24 °C as compared to 4 °C. A convenient elution condition was ten minutes at 4 °C.

A linear relationship should exist between platelet concentration and Ig yield. Because high concentrations of platelets could buffer the acid and alter Ig yield, the effect of platelet concentration on the linearity of the Ig elution was evaluated. Figure 4 shows a linear relationship between IgG, IgA, and IgM and the number of platelets up to 2 × 10^8 platelets/700 µL of acidified platelet suspension.

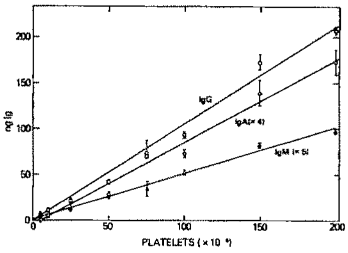

Fig 4. Linearity of Ig elution. Duplicate platelet samples were suspended in 200 µL of saline to which was added 500 µL of 50 mmol/L of H_3PO_4, 0.5% bovine serum albumin (BSA), pH 2.8. IgG (□), IgA (○), and IgM (△).

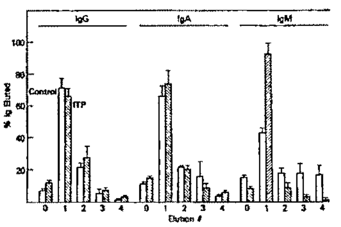

Fig 5. Multiple elutions of Igs from pooled platelets of three normal individuals (open bars) and four idiopathic thrombocytopenic purpura (ITP) patients (hatched bars) in duplicate. Error bars are 1 SEM. Zero elution refers to the Ig present in the supernatant of the centrifuged saline suspension that was never acidified, and the value represents percentage of total eluted material.

A single elution was used for most experiments. However, this did not appear to release 100% of the Igs from the platelets (Fig 5). As judged by summation of four sequential elutions, the first elution released ~70% of platelet-associated IgG and IgA from both control and ITP platelets. IgM release in the first elution of control platelets was ~43% whereas that of ITP platelets was ~90% in the first elution. The variation in the yield of Igs from the first elution is ≤10%. Because IgM levels were quite small and near the limits of sensitivity of the assay, there was some added uncertainty in the percentages of total IgM in elutions of control platelets. Platelets were also disrupted by sonication of freeze-thawing and were then acid-eluted and centrifuged at 20,000 g for 30 minutes; this increased the single elution yield of IgG, IgA, and IgM between 50% and 100%.

The amounts of Igs associated with normal platelets and ITP platelets are shown in Fig 6. Average levels of IgG, IgA, and IgM, from a sample of 13 normal donors are 1.4 ± 0.13, 0.72 ± 0.18, and 0.078 ± 0.018 fg per platelet, respectively (mean ± SEM). The ratio of normal value of PAIgA to PAIgG (0.5) appears to be higher than the ratio of average plasma levels (0.17), whereas the ratio of normal value of PAIgM to PAIgG (0.056) is close to that seen in plasma (0.074). Similarly, the ratio of PAIgG to platelet albumin (0.25) is not different from the ratio normally found in serum (0.26).

The mean platelet-associated Ig levels were elevated for all three Ig classes in ITP patients. In this series of eight patients (two were tested twice with at least one month between samples), IgG was elevated 70-fold; IgA was elevated 125-fold, and IgM was elevated 2,080-fold. The platelet counts for the ITP patients were, from bottom to top in the IgG

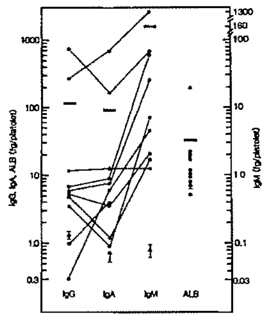

Fig 6. Platelet-associated serum proteins in normal donors and patients with idiopathic thrombocytopenia purpura (ITP). Individual values for ITP patients (●); means for this group are solid horizontal bars. Triangles are the mean ± SEM for 13 normal donors. Lines connect values obtained on a single platelet sample.

column (× $10^3/\mu L$: A, 215; B, 200; C, 27; D, 6; E, 9; F, 21; G, 45; H, 6; I, 2; and J, 5). Samples A and H and samples C and I were taken from the same individuals. Samples A and B were taken from ITP patients in remission. PRP and platelets from a saline wash of the initial red cell fraction were pooled for sample J. Platelet-associated human serum albumin (PAA) was also measured in a different group of ten ITP patients and 12 controls; it was elevated: normal, 7.7 ± 1.5 fg per platelet; ITP, 33 ± 18 fg per platelet (mean ± SEM). These PAA levels are from a different group of patients than that used for the Ig study and did not include two of the patients with the highest Ig levels. Therefore, the PAA data are not strictly comparable to the PAIg measurements except that the mean values of all measured platelet-associated serum proteins were elevated in ITP patients. Platelet counts of ITP patients on whom PAA levels were obtained were, from bottom to top in the ALB column (× $10^3/\mu L$: 73, 50, 30, 18, 80, 54, 10, 21, 27, and 4).

There were two examples of normal PAIgG with elevated PAIgA or PAIgM and one instance of normal PAIgA and elevated PAIgG and PAIgM. Linear regression analysis was made to determine if there was a correlation between the levels of different Ig classes. There was no significant correlation between IgG and IgA ($r = 0.47$, $n = 10$) or IgG and IgM ($r = 0.24$, $n = 9$); however, there was a significant correlation between IgA and IgM ($r = 0.95$, $n = 9$, $P > .01$). This latter correlation disappears if the patient with the highest Ig levels, a pediatric ITP patient, is removed from the group ($r = 0.31$, $n = 8$). Finally, there is high variability in the patient groups: (mean ± SEM) IgG 104 ± 74; IgA 90 ± 70; and IgM 162 ± 142 fg per platelet.

DISCUSSION

Others have used SPRIA or enzyme-linked procedures for the measurement of platelet-associated IgG.[9,14–16] The present modification, using an antibody-antigen-antibody procedure to assay soluble and eluted platelet-associated proteins permits efficient binding of the antigen of interest to the microtiter plate regardless of the concentration of other proteins in the sample. This is in contrast to procedures in which the antigen is bound directly to the microtiter plate, in which case the concentration of the antigen of interest must be relatively high for efficient quantitation because all proteins in cell extracts and eluates or serum samples compete for binding to a degree approximately proportional to their concentration. The SPRIA described is therefore more sensitive than previously described assays for measuring specific proteins in mixture with other proteins. Another advantage of the acid elution SPRIA procedure, in contrast to measurement using monoclonal anti-IgG or protein A binding to intact platelets,[17–19] is the ability, with no ambiguity, to relate the eluted, soluble Ig to a purified, soluble reference Ig by a standard SPRIA curve. This eliminates assumptions about the availability, affinity, and stoichiometry of binding sites of platelet membrane-associated IgG molecules for assay reagents. Reports using procedures in which such assumptions are used in final calculations[18,19] gave normal PAIgG values 15 to 30 times lower than that determined in this study and most others (see ref. 3, p 315).

The nature of the antibody preparation has significant effects on the SPRIA technique described. Microtiter plates coated with affinity-purified antibodies have a much higher capacity and potentially greater selectivity than does the equivalent antiserum or even purified IgG fraction. Polyclonal antibodies, because of their heterogeneity, generally give binding curves which reliably span up to 2 logs of antigen concentration, whereas monoclonal antibodies have much steeper antigen binding curves. The latter situation may require a larger number of dilutions to be certain that unknowns fall on a reliable portion of the standard curve.

Selectivity of the antibodies used in this report is also a significant point. Because at least one report specifically denied the presence of IgA and IgM on normal platelets,[5] it was necessary to demonstrate that the antibodies used in this procedure were sufficiently specific to avoid spurious results. The cross-reactivity of each Ig assay system for other Ig classes was negligible.

The acid elution of platelet-associated proteins is a convenient nondenaturing procedure that is much less disruptive of platelets and their membranes than either detergent[20] or freeze-thaw sonication.[5] Platelets treated with detergent become nonrecognizable as cells, and remaining insoluble material appears as debris. Although sonication treatment is difficult to compare among laboratories, this treatment usually results in total mechanical disruption of platelet membranes and solubilization of a substantial amount of intracellular material. Acid elution at pH 2.8 leaves platelets morphologically distinguishable by electron microscopy and does not produce the fragmentation and debris formation that is characteristic of the more disruptive procedures. The percentage of recovery of total platelet-associated proteins from the acid elution is reproducible and appears to be identical for normal and ITP platelets with respect to IgG and IgA. Although the pattern of recovery for IgM appears to be different for normal and ITP platelets, this could reflect the small quantities of IgM released from control platelets relative to the sensitivity of the assay, particularly in eluates subsequent to the first. Whether or not the SPRIA we used measures only surface proteins on platelets is open to question. We did measure PAIgG of 20 normal controls using the antiglobulin consumption assay[21] with the same antiglobulin reagents and standard IgG used in the SPRIA. The mean value for normal PAIgG was 1.9 ± 1.5 (2 SD) fg per platelet as compared with the mean SPRIA value of 1.4 fg per platelet. Because the antiglobulin consumption assay and the SPRIA measure similar amounts of PAIgG, the assumption by some workers that the former test measures only surface IgG may also apply to the SPRIA, even though the true value for surface PAIgG remains controversial.[19] However, we do not claim to measure only surface proteins by the SPRIA but have shown that the proteins measured are soluble, antigenically intact, and reproducibly measurable by an unambiguous quantitative assay.

This investigation demonstrates two main points. First, it has been shown that there are measurable levels of IgA, IgM, and albumin, as well as of IgG, on normal platelets. Second, all three immunoglobulin classes associated with platelets and even platelet-associated albumin were elevated in most of the ITP patients studied.

Measurement of PAIgG is a frequently used diagnostic test in ITP. Elevations of PAIgG are often interpreted as the amounts of specific antiplatelet antibody bound to platelets and responsible for their destruction. However, we[3,22] and others[23,24] have questioned this interpretation for several reasons. The increased quantities of PAIgG involved in ITP are higher by one to several orders of magnitude than cellular antibody levels causing platelet destruction in well-defined disorders of immunologic origin involving isoantibodies or drug antibodies,[3] and are often more than tenfold the amounts of these antibodies that saturate platelets in vitro.[3] If the high levels of immunoglobulin associated with platelets in ITP are responsible for platelet destruction, the mechanism of destruction must be significantly different from that caused by high-affinity antiplatelet isoantibodies or drug antibodies. Moreover, highly elevated PAIgG levels similar to those found in ITP have also been associated with thrombocytopenias of apparent nonimmune origin.[23] Other major problems of interpretation are raised by the lack of correlation between direct PAIgG measurements in ITP and indirect serologic assays for antiplatelet antibodies, even when such assays are performed in the same test system used for measuring the direct PAIgG,[22,25] and by the finding of elevated albumin levels associated with platelets from ITP patients.[26,27] Finally, the demonstration of rapid increases in platelet-associated dog IgG and dog albumin when dogs are made acutely thrombocytopenic by the infusion of rabbit anti-dog platelet sera[26] further supports the consideration that elevations of PAIgG in ITP, may not reflect the actual amounts of specific antiplatelet antibody responsible for platelet injury and destruction. Antibodies responsible for ITP may destroy platelets at the same low levels per platelet as do isoantibodies or drug antibodies that are not detectable by direct assays on circulating platelets. Platelet destruction may then lead to high elevations of platelet-associated proteins by a secondary nonspecific phenomenon.

One postulated mechanism for elevating PAIgG is promotion of accessibility of platelet membrane Fc receptors by injurious specific ITP antibody, leading to nonspecific immunoglobulin binding.[28] Certain aspects of nonspecific binding of IgG, and presumably other Igs, however, remain unclear. Although a platelet Fc receptor of IgG has been characterized[29] and quantitated,[30] it has not been proven that this type of binding can account for the relatively large amount of IgG associated with extensively washed normal platelets (~100-fold that for a normal red cell) or the many-fold increases in PAIgG that may accompany ITP since the IgG "specifically" bound by Fc receptor was reported to be removed by a single PBS wash.[30] Moreover, Fc binding does not account for elevated platelet-associated albumin

We have proposed an alternate mechanism for elevation of platelet-associated immunoglobulin and albumin that appears to be as reasonable as other theories to explain the observed phenomena; namely, that entrapment of plasma components in the platelet canalicular system or in resealed cell membrane fragments may account for the large amounts of plasma proteins associated with platelets normally and in pathological states when fragmentation is apparently augmented by platelet destruction.[22] Growing evidence shows that a component of the increase in immunoglobulins associated with platelets in ITP involves a nonspecific process whether by this postulated "trapping" mechanism or other mechanisms. The size of the nonspecific component and the exact mechanism of the phenomenon await further studies.

Reevaluation of Cytochrome b and Flavin Adenine Dinucleotide in Neutrophils From Patients With Chronic Granulomatous Disease and Description of a Family With Probable Autosomal Recessive Inheritance of Cytochrome b Deficiency

By Yohichiroh Ohno, E. Stephen Buescher, Robert Roberts, Julia A. Metcalf, and John I. Gallin

Chronic granulomatous disease (CGD) is a genetically heterogeneous syndrome characterized by a microbial killing defect of polymorphonuclear leukocytes (PMNs) due to lack of superoxide O_2^- generation. Recent studies indicate that the neutrophil O_2^--generating system consists of at least two components, flavoprotein—flavin adenine dinucleotide (FAD)— and cytochrome b. We evaluate the cytochrome b and FAD content in PMN from 30 CGD patients. The method for quantitating cytochrome b was modified by using PMN sonicates incubated with azide plus hydrogen peroxide. With this approach, several absorption peaks corresponding to myeloperoxidase and eosinophil peroxidase, which overlap with peaks of cytochrome b, were obliterated from reduced-minus-oxidized spectra, whereas the peaks of cytochrome b were not and could be readily quantitated. Cytochrome b was detected in PMNs from all 24 normal adults (47.4 ± 2.9 pmol/7.5 × 10^6 cells), was absent in PMNs from 11 male CGD patients and one female CGD patient but was present in normal amounts in PMNs from nine male and nine female CGD patients. Stimulated nitroblue tetrazolium (NBT) tests performed on PMNs from mothers of CGD patients indicated that cytochrome b deficiency was associated with X-linked inheritance, except in one case in which probable autosomal recessive inheritance was demonstrated. The PMN NBT test of the mother of another male patient without cytochrome b deficiency suggested an X-linked form of inheritance. In related studies, the FAD content in PMN particulate fractions was reduced in 4 of 28 CGD patients studied. All four CGD patients with reduced FAD lacked cytochrome b. However, three patients with cytochrome b deficiency had normal FAD. Thus, the results indicate that PMN cytochrome b deficiency is observed in most X-linked and in some autosomal recessive CGD, that cytochrome b deficiency may be associated with FAD deficiency, and that cytochrome b and FAD are normal in most patients with non-X-linked CGD.

POLYMORPHONUCLEAR leukocytes (PMNs) release superoxide anion (O_2^-), hydrogen peroxide, and other oxygen radicals when stimulated with particulate stimuli such as bacteria or fungi or with soluble stimuli such as phorbol esters, chemotactic peptides, and calcium ionophore.[1] Superoxide anion generated in the plasma membrane or phagosomal membrane by reduction of oxygen by electrons originating from neutrophil glucose-6-phosphate dehydrogenase (NADPH), dismutates to form hydrogen peroxide.[2,3] The hydrogen peroxide contributes to the microbicidal activity of neutrophils in cooperation with myeloperoxidase and halide.[4] Neutrophils from patients with chronic granulomatous disease (CGD) cannot produce superoxide and hydrogen peroxide when exposed to metabolic stimuli. As a result, patients with CGD are highly susceptible to bacterial infections. The disease may be classified into several hereditary types, including X-linked,[5] autosomal recessive,[5] and, possibly, autosomal dominant types.[6] Deficiency of NADPH,[7] glutathione peroxidase,[8] and NADPH oxidase have been thought to be the basis for the disease in different patients.

Recently, the NADPH oxidase has been considered a multicomponent system. A nonmitochondrial cytochrome b probably is involved. Some evidence indicates that the cytochrome b functions as a terminal component of the NADPH oxidase in donating electrons to oxygen.[9,10] The cytochrome b has dual subcellular localization and has been localized to the plasma membrane and an intracellular pool that cosediments with specific granules.[11–13] Flavoprotein, flavin adenine dinucleotide (FAD), is probably another component in the O_2^- generating system[14–18] and seems to be a proximal constituent of the electron-transport chain which accepts electrons directly from NADPH.[18]

Segal et al studied the content of cytochrome b in PMNs from 27 patients with CGD[19] and suggested that neutrophil cytochrome b deficiency was related to an X-linked inheritance of the disease. In addition, several reports indicate that the FAD content in the particulate fractions of neutrophils is decreased in some CGD patients.[16,17,20,21] Of eight patients reported previously with PMN FAD deficiency, seven patients had PMN cytochrome b deficiency. In the current study, the cytochrome b content in neutrophils from 30 CGD patients was measured by a modified method that removes an artifact of eosinophil peroxidase. In addition, FAD content was quantitated in 28 CGD patients. Although most patients with CGD who had cytochrome b deficiency had an X-linked pattern in their disease, in one family the inheritance was best explained as autosomal recessive. In another family with X-linked inheritance, neutrophil cytochrome b was normal. Of 28 patients examined, FAD was reduced in four patients whose neutrophils also lacked cytochrome b.

MATERIALS AND METHODS

Patients The diagnosis of CGD was determined by defective reduction of phorbol myristate acetate (PMA)-stimulated nitroblue tetrazolium (NBT) dye and impaired killing of *Staphylococcus aureus* by neutrophils from the patients.[6] Severe G6PD deficiency was excluded by demonstrating that the patients' cells responded to methylene blue with enhanced hexose monophosphate shunt activity.[6] Thirty patients from patients referred to the National Institutes of Health for evaluation of compromised host defenses were diagnosed as having CGD

Preparation of cell sonicates. PMNs were collected by centrifugation on Ficoll-Hypaque and dextran sedimentation as previously described.[22] For one study, eosinophils were collected from the blood of a patient with microfilaria infection, as described elsewhere.[23] This method yields almost pure populations of eosinophils (>98% purity) Cells were suspended at a concentration of 7.5×10^6/mL in 50 mmol/L of 3-[*N*-morpholino] propane-sulfonic acid (MOPS), 100 mmol/L of KCl, pH. 7.0, sonicated for two cycles of ten seconds at 18 W at 4 °C, and solubilized by addition of sodium deoxycholate (0.1% of the final concentration).

Treatment of cell sonicates with azide plus hydrogen peroxide. Cell sonicates (7.5×10^6/mL) were incubated with 0.5 mmol/L of hydrogen peroxide plus 5 mmol/L of sodium azide at room temperature for 15 minutes. In some experiments, cell sonicates were incubated with 10 mmol/L of glucose plus 50 mU/mL of glucose oxidase in the presence of 5 mmol/L of azide at 37 °C for 30 minutes. The glucose–glucose oxidase system is an effective hydrogen peroxide generating system.[24] After incubation, the sonicates were cooled and kept in melting ice until spectral assay.

Reduced-minus-oxidized difference spectra. One milliliter of a sonicated sample (7.5×10^6 cells) was put in a cuvette. The absolute spectra of the sample were recorded from 600 nm to 400 nm with a Perkin-Elmer lambda-3 spectrophotometer and stored in an attached computer (Perkin-Elmer 3600 data station). The sample was reduced with the addition of solid sodium dithionite (1 to 2 mg). The absolute spectra of the reduced sample was recorded from 600 nm to 400 nm and stored. Reduced-minus-oxidized difference spectra were created by subtracting the absolute spectra of the sample from the absolute spectra of the reduced sample with the computer. Cytochrome b was measured in PMN sonicates treated with azide plus hydrogen peroxide as described in the first part of the Results section, using an absorption coefficient of 106 mmol/L^{-1} cm^{-1} at the Soret peaks[25] and expressed as pmol/7.5 $\times 10^6$ cells.

Subcellular fractionation. Subcellular fractions were collected from normal human neutrophils and from CGD neutrophils lacking cytochrome b by whole cell assays. The method for obtaining subcellular fractions with Percoll was described previously.[13] In brief, PMNs (1.5×10^8) were disrupted by nitrogen cavitation. The postnuclear cavitate was layered on a discontinuous gradient of 37.4% and 97.4% Percoll. Gradients were centrifuged for 15 minutes at 33,000 g. The postnuclear cavitate was separated into plasma membrane-rich, specific granule-rich, azurophil granule-rich, and cytosolic fractions on the basis of well-described enzyme marker assays described below. Collected fractions were separated from the Percoll and resuspended in a MOPS-KCl buffer in a concentration of 0.2 mg/mL of protein. Alkaline phosphatase was assayed with *p*-nitrophenyl phosphate as a substrate.[22] Vitamin B_{12} binding protein was measured with ^{57}Co-vitamin B_{12} (Amersham, Arlington Heights, Ill).[22] Myeloperoxidase and cytochrome b in subcellular fractions were assayed with reduced-minus-oxidized difference spectra. An absorption coefficient of 75 mmol/L^{-1} cm^{-1} at 472 nm was used to quantitate myeloperoxidase.[26] Cytochrome b was measured with the samples treated with azide plus hydrogen peroxide, using an absorption coefficient of 106 mmol/L^{-1} cm^{-1} at the Soret peak.[25] The protein was determined with Coomassie blue as described previously.[27]

Assay of flavins FAD and flavin mononucleotide (FMN) were determined in the particulate fraction collected from activated PMNs as described previously.[20] PMNs (10^8 cells) were activated by incubation with 100 ng/mL of PMA at 37 °C for five minutes in Krebs-Ringer's phosphate buffer with 5.5 mmol/L of glucose, pH 7.4 After activation, cells were washed twice, suspended in 0.34 mol/L of sucrose, and sonicated for three cycles of ten seconds at 18 W at 4 °C. The sonicates were centrifuged at 500 g for ten minutes. The postnuclear supernatant was centrifuged at 27,000 g for 20 minutes at 4 °C. The pellet was resuspended in 0.34 mol/L of sucrose and recentrifuged at 27,000 g at 4 °C. The particulate fraction was washed once more and resuspended in 0.1 mol/L of potassium phosphate buffer with 0.1 mmol/L of EDTA, pH 7.7, to the concentration of 0.4 mg/mL of protein. FAD and FMN were quantitated by the method of Faeder and Siegel[28] Triton X-100 (Rohm and Haas, Philadelphia) was added to particulate fractions to a final concentration of 0.1%. The particulate fractions were immersed in boiling water for four minutes and cooled rapidly in melting ice water. Insoluble materials were removed by centrifugation in an Eppendorf microfuge for ten minutes at 4 °C. The fluorescence of the samples was measured with the excitation wavelength of 450 nm and the emission wavelength of 535 nm, using a Perkin-Elmer LS-5 fluorescence spectrophotometer. Thereafter, the pH of the solutions was lowered to 2.6 with 1 *N* HCl, and the fluorescence was then determined. Standard curves for flavins at pH 7.7 and pH 2.6 were determined with commercially obtained FAD and FMN (Sigma Chemical Co, St Louis).

Neutrophil functions. The PMA-stimulated NBT test[29] and superoxide production,[22] were performed as described previously using 20 ng/mL of PMA or 1 *u*mol/L of formyl-methionyl-leucyl-phenylalanine (FMLP) as the stimulus.

RESULTS

Modification of difference spectra assay used for measurement of cytochrome b. Several peaks were observed in reduced-minus-oxidized difference spectra from normal neutrophils (Fig 1). A prominent positive peak of absorption at 472 nm and a negative peak at 420 nm were due to absorption by myeloperoxidase.[30] A shoulder observed at 452 nm corresponded to the absorption of eosinophil peroxidase. A small positive peak at 558 nm and a prominent peak at 424 nm were the α and Soret peaks of cytochrome b, respectively.[10] Previous workers have used the α-peak (558 nm) to quantitate cytochrome b,[19] but the assay is difficult when PMNs contain many eosinophils, as occurs in leukocytes obtained from many patients with CGD since eosinophil peroxidase absorbs at 450 nm and 560 nm. For example, the difference spectra of eosinophils separated from a patient with hypereosinophilia (Fig 2) revealed a prominent positive

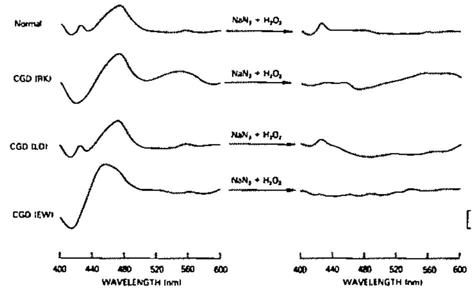

Fig 1. Reduced-minus-oxidized difference spectra of sonicates from normal and chronic granulomatous disease polymorphonuclear leukocytes (CGD PMNs). Normal or CGD PMNs (7.5×10^6/mL) in 3-[*N*-morpholino] propane-sulfonic acid (MOPS)-KCl buffer, pH 7.0 were sonicated at 18 W for two cycles of ten seconds. The sonicates were incubated with 5 mmol/L of azide and 10 mmol/L of glucose plus glucose oxidase (50 mU/mL) for 30 minutes at 37 °C. Tracings (left) show dithionite reduced-minus-oxidized difference spectra of a PMN sonicate; tracings (right column) show difference spectra of a PMN sonicate incubated with azide plus hydrogen peroxide generating system.

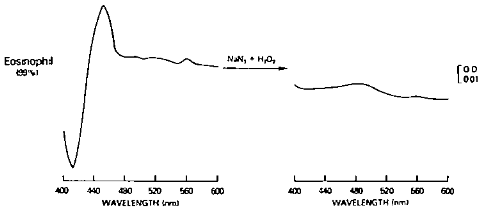

Fig 2. Reduced-minus-oxidized difference specta of eosinophil sonicates. The difference spectra of eosinophils was recorded in the same scale and the same number of cells as the polymorphonuclear leukocytes (PMN) sonicates shown in Fig 1. Tracing (left) shows dithionite reduced-minus-oxidized difference spectra of eosinophil sonicates; tracing (right) shows difference spectra of an eosinophil sonicate incubated with 5 mmol/L of azide plus 0.5 mmol/L of H_2O_2.

peak at 450 nm, a negative peak at 414 nm, and a small positive peak at 560 nm; these correspond to the maxima of the spectra of eosinophil peroxidase.[31] Difference spectra of PMN sonicates from one CGD patient (E.W.) showed a prominent shoulder at 452 nm due to a high content of eosinophil peroxidase (Fig 1). A small peak observed at 560-nm absorption, corresponding to eosinophil peroxidase, makes assay of cytochrome b at 558 nm impossible.

Therefore, to improve quantitation of cytochrome b, we developed a new technique to delete peaks of myeloperoxidase and eosinophil peroxidase. As shown in Fig 1 and Fig 2, the peaks of myeloperoxidase and eosinophil peroxidase were completely obliterated by treating the cell sonicates with azide plus hydrogen peroxide, and an α peak and a Soret peak of cytochrome b were clearly observed. Difference spectra of PMN sonicates from two male CGD patients suspected of X-linked CGD (R.K. and E.W.) are shown in Fig 1. Treatment of the sonicated sample with azide plus hydrogen peroxide obliterated the absorption peaks of myeloperoxidase and eosinophil peroxidase, clearly delineating the absence of the α and Soret peaks of cytochrome b. In a female patient with non-X-linked CGD (L.O.), absorption peaks for myeloperoxidase and cytochrome b were observed before treatment with azide plus hydrogen peroxide (Fig 1). After treatment with azide plus hydrogen peroxide, the α and Soret peaks of cytochrome b were seen.

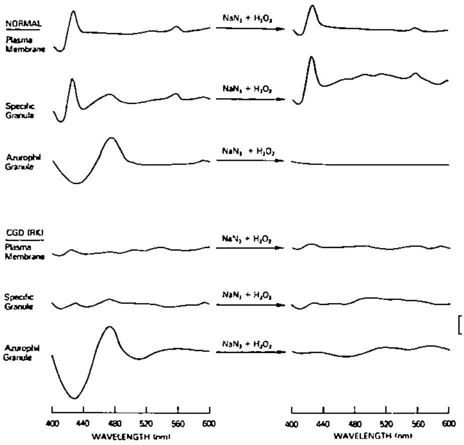

Fig 3. Reduced-minus-oxidized difference spectra of subcellular fractions isolated from normal and chronic granulomatous disease polymorphonuclear leukocytes (CGD PMNs). Normal PMNs and PMNs from a patient with CGD (R.K.) were disrupted by nitrogen cavitation. The subcellular fractions were separated from the postnuclear cavitates with Percoll-density gradients. The fractions were adjusted to 0.2 mg/mL of protein. The reduced-minus-oxidized difference spectra of subcellular fractions and those fractions treated with azide plus hydrogen peroxide were recorded.

To determine whether treatment with hydrogen peroxide plus azide affects the absorption of cytochrome b, we studied the effect of azide plus hydrogen peroxide on PMN subcellular fractions. Marker proteins in each fraction are shown in Table 1. The membrane-rich fraction was enriched in alkaline phosphatase. The specific granule-rich fraction contained a large amount of vitamin B_{12} binding protein. Myeloperoxidase was mainly enriched in the azurophil granule-rich fraction, but the specific granule-rich fraction also included a small amount of myeloperoxidase. Cytochrome b was located on both the plasma membrane-rich and specific granule-rich fractions as reported previously.[12,13] In Fig 3, the difference spectra of each fraction before and after treatment with azide plus hydrogen peroxide are shown. Following treatment with azide plus hydrogen peroxide, both the positive peak at 472 nm and the negative peak at 435 nm were eliminated, indicating that myeloperoxidase was successfully deleted from the azurophil granule-rich and specific granule-rich fractions. The height of a Soret peak (424 nm) of cytochrome b observed in the membrane-rich fraction, which lacked myeloperoxidase, was not decreased by the treatment. Therefore, this peak was used for all measure-

Table 1. Marker Proteins in Subcellular Fractions From Neutrophils

Fraction	Alkaline Phosphatase (mU/mg of Protein)	Vitamin B_{12} Binding Protein (ng Vit B_{12} Bound/mg of Protein)	Myeloperoxidase (nmol/mg of Protein)	Cytochrome b (nmol/mg of protein)

Separation of subcellular fractions and the assay of various proteins are described in Materials and Methods section. Data for the normal PMNs are mean ± SEM of nine preparations whereas CGD data are from a typical experiment.

ments of cytochrome b unless indicated otherwise. We did not select the α peak for measurement of cytochrome b because the height of the Soret peak was five times higher than the α peak.

Cytochrome b in subcellular fractions of CGD PMNs. With the above method, the difference spectra of subcellular fractions from CGD cells that lacked cytochrome b were examined. Distribution of alkaline phosphatase, vitamin B_{12} binding protein, and myeloperoxidase in each subcellular fraction was the same as in normal PMNs (Table 1). Although peaks of myeloperoxidase absorption were clearly observed, the absorption peaks corresponding to cytochrome b were not seen (Fig 3). Only a minimal positive peak at 429 nm and its negative peak at 410 nm were observed in the plasma membrane-rich and specific granule-rich fractions after azide plus H_2O_2 treatment (Fig 3). These small peaks at the Soret region probably come from contaminated hemoglobin or from hemochromes in the mitochondria or microsome fractions. The contribution of substances other than cytochrome b to the Soret peak observed in the difference spectra of the subcellular fractions was negligible.

Measurement of cytochrome b in normal and CGD PMNs. PMNs from normal adults contained 47.4 ± 2.9 (mean ± SEM, n = 24) pmol of cytochrome b per 7.5 × 10^6

Cytochrome b in PMNs from CGD patients was measured from difference spectra of PMN sonicate treated with azide plus hydrogen peroxide as shown in Fig 1.

*$P < 0\ 05$ *v* normal, Student's *t* test.

‖No significant difference as compared to normal

†Brothers; ‡brothers; §siblings (D J and S J . nonhomozygous twins), ¶siblings; **homozygous twins, ††C.H is a fraternal aunt of L H , suspected of autosomal dominant inheritance.[8] Parents of the patients (H.P., M B., K L., and C.T.) are first cousins. Cytochrome b content in PMNs from 24 normal adults was 47.4 ± 2.9 pmol/7 5 × 10^6 cells. FAD content of PMN particulate fraction from 14 normal adults was 104.7 ± 9.2.

NT, not tested.

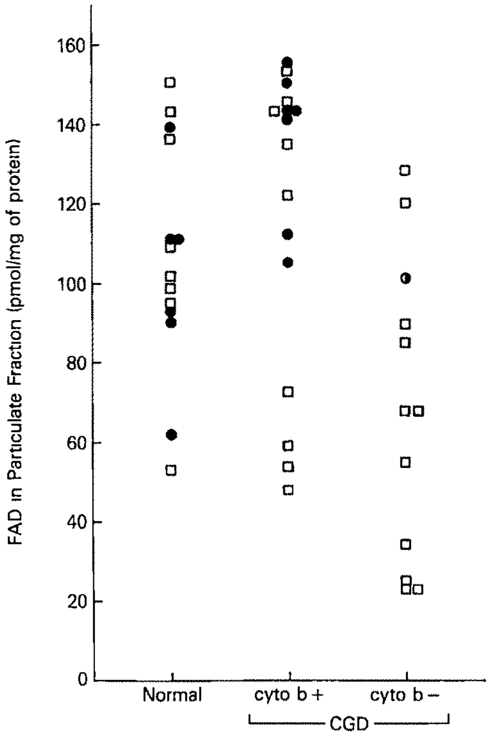

Fig 4. Flavin adenine dinucleotide (FAD) in the particulate fraction of normal and chronic granulomatous disease (CGD) neutrophils. Polymorphonuclear leukocytes (PMNs) were activated by incubation with 100 ng/mL of phorbol myristate acetate (PMA) for five minutes at 37 °C. The cells were washed twice and sonicated. The postnuclear supernatant was centrifuged at 27,000 g for 20 minutes at 4 °C. The pellet, (PMN particulate fraction) was assayed for FAD as described in the Materials and Methods section. Females (●); males (□); patient A.V. (O).

cells. Cytochrome b was absent from PMNs from 11 male patients with CGD (Table 2). Cytochrome b was detected in normal amounts in PMNs from nine other male patients with CGD (41.4 ± 5.7 pmol/7.5 × 10^6 cells) (Table 2). PMNs from nine female patients with CGD also contained normal amounts of cytochrome b (48.6 ± 5.1 pmol/7.5 × 10^6 cells), although PMNs from a female patient (A.V.) totally lacked cytochrome b (Table 2).

FAD in neutrophil fractions. FAD in particulate fractions of normal PMNs was 104.7 ± 9.2 pmol/mg of protein (n = 14). However, significantly reduced FAD was observed in four CGD patients with associated cytochrome b deficiency (Fig 4) The other patients had normal PMN FAD. The data pertaining to FAD in each CGD patient are included in Table 2.

A subcellular deficiency of FAD has been suggested as the basis of a defect in some patients.[21] To assess this possibility, neutrophils from three patients with low normal FAD, (M.B., J.H., and R.D., Table 2), were fractionated into cytosol-, membrane-, specific granule-, and azurophil granule-enriched fractions as described in Table 1. All fractions from the CGD patients contained FAD; the only possible deficiency noted was in the specific granule-enriched fraction of M.B., which contained 101 pmol/mg protein *v* 219 ± 44 pg/mg protein for the three normal subjects. Thus, although a subcellular deficiency of FAD may exist in one of these patients, the magnitude of the defect is not dramatic.

A family with probable autosomal recessive cytochrome b deficiency (Table 3). Although most of our patients with cytochrome b deficiency had an X-linked recessive pattern of inheritance, the disease appeared to be inherited in an autosomal recessive pattern in one female patient (A.V.). The PMA-stimulated NBT test confirmed that the patient PMNs could not reduce NBT after stimulation. The NBT scores of PMNs from the mother and father and three male siblings were normal. Superoxide generation was totally absent in the patient's PMNs. PMNs from the mother, father, and two siblings showed a common pattern of superoxide production; normal response to PMA but reduced response to fMet-Leu-Phe.

The cytochrome b of the patient's PMNs was not detected in three separate examinations. The cytochrome b content of PMNs from the mother and the father were significantly reduced to about half-normal (Table 3) although PMNs from two of the patient's siblings with somewhat reduced O_2^- production to fMet-Leu-Phe contained normal amounts of cytochrome b. FAD of PMN particulate fractions were normal in every member of the family, including the patient.

DISCUSSION

The most commonly used method for quantitating cytochrome b is the method of Segal et al who used the α peak of cytochrome b (558 nm) absorbance to measure neutrophil

cytochrome b.[19] With this approach, a peak of eosinophil peroxidase (560 nm) overlaps the α peak of cytochrome b,[25] making it difficult to measure cytochrome b in PMNs containing eosinophils, which in our experience are frequently mildly elevated in CGD. We overcame this problem by treating PMN sonicates with azide and hydrogen peroxide. This method obliterated the absorption peaks of myeloperoxidase and eosinophil peroxidase without significant alteration of cytochrome b absorption. We have shown previously that azide plus hydrogen peroxide irreversibly inactivates the activity of myeloperoxidase and eosinophil peroxidase.[32]

PMN cytochrome b of 24 normal adults and 30 CGD patients was measured. Cytochrome b was detected in cells from each normal adult (47.4 ± 2.9 pmol/7 5 × 10^6 cells, n = 24). This value was slightly lower than those described by Segal et al,[19] probably because the absorption at 558 nm they measured represented the α peak of cytochrome b plus the 560 mm absorption peak of eosinophil peroxidase. In 11 of 20 male CGD patients, PMN sonicates lacked cytochrome b (Table 2). Neutrophils from mothers of the patient group were examined for the stimulated NBT test. A mosaic pattern of normal and abnormal neutrophils was found in all patients, indicating heterozygous carriers and an X-linked trait of the disease (Table 2). On the other hand, cytochrome b was present in neutrophils from nine other males with CGD. Neutrophils from five mothers had a normal NBT score and one, R.D., had a mosaic pattern (Table 2). Cytochrome b content was normal in PMNs from nine female patients with CGD. The neutrophil NBT test from each mother in this group of female CGD patients was normal (Table 2).

As reported previously, X-linked transmission and autosomal recessive transmission of CGD are commonly observed,[5,6] and one family with autosomal dominant inheritance has been reported.[6] A recent study suggested that the autosomal recessive form of CGD has less severe symptoms than does the X-linked form of the disease.[33] We saw no difference in symptoms among our patient groups. However, this may be because the use of prophylactic bactrim therapy[6] makes comparison of disease severity among the patient groups difficult to interpret. Segal et al suggested that the cytochrome b content in neutrophils from CGD patients is valuable for determining the type of genetic transmission.[19] Our study supports Segal's conclusion except for two patients. One patient (A.V.) is a female with cytochrome b deficiency. Extreme lyonization of a heterozygote is not a likely explanation for the inheritance in A.V. because the NBT score of the mother's PMNs was not compatible with X-linked CGD. Furthermore, the cytochrome b content in PMNs of both her mother and father was reduced to half-normal, strongly suggesting an autosomal recessive type of cytochrome b deficiency. In addition, the superoxide production of the mother and father's PMNs was reduced when FMLP, but not PMA, was used as a stimulant (Table 3). Abnormal superoxide production was also observed in PMNs from two of her siblings, although PMN cytochrome b of the siblings was not sufficiently reduced to indicate that they were heterozygotes (Table 3). Another description of a family with an autosomal form of cytochrome b deficiency appeared in a recent paper.[34] Thus, a phenotype of neutrophil cytochrome b deficiency can be separated into two genetic types, X-linked or autosomal recessive. The synthesis of mature cytochrome b must require several processes; putative gene activator proteins, transcription, RNA processing, nuclear to cytoplasmic transport of mRNA, translation, and posttranslational modification including incorporation of the heme moiety. If any step is defective or lacking, cytochrome b will be undetectable by spectroscopy. The identification of families with autosomal recessive cytochrome b inheritance furthers our understanding of the genetic mechanism of neutrophil cytochrome b production Probably a structural gene for cytochrome b will be located on an autosomal chromosome. Thus, a mutation of one of the homologous autosomal chromosomes (heterozygote) would lead to a half-normal cytochrome b. The X chromosome may have a gene encoding a putative cytochrome b gene activator protein that may positively switch on the transcription of the cytochrome b gene.[35] Alternatively, the X chromosome may have an "enhancer element" that ensures accurate and efficient initiation of transcription.[36] Further understanding of the molecular defect of CGD patients with cytochrome b deficiency will require purification of cytochrome b and cloning of the cytochrome b gene.

The other patient who did not fit the generalization that all X-linked CGD patients have cytochrome b deficiency is a male CGD patient (R.D.) strongly suspected of X-linked CGD from the NBT score of his mother's PMNs; however, the patient's PMNs contained normal amounts of cytochrome b (Table 2). Moreover, the mother's PMNs also contained normal amounts of cytochrome b (49.7 pmol/ 7.5 × 10^6 cells). This is important because heterozygotes of X-linked cytochrome b deficiency should show reduced PMN cytochrome b according to the NBT score.[19] The patient's PMNs also contained normal FAD. Therefore, in patient R.D., deficiency of another substance controlled by the X-chromosome is suspected. In this respect, a recent report suggested a requirement of a cytosolic factor for O_2^- generation,[37] which may be missing in patient R.D.

Several publications reported reduced FAD in CGD neutrophils. Cross et al reported three cases of X-linked CGD, in whom neutrophil membrane fractions contained 50% of the normal level of FAD[16]; these patient's neutrophils also lacked cytochrome b. In contrast, in three cases with autosomal recessive CGD, FAD and cytochrome b were normal. Cross et al suggested that there is a close association between FAD and cytochrome b. Gabig and Lefker reported three male CGD patients with FAD deficiency of the neutrophil particulate fraction[20]; two of the patients also had neutrophil cytochrome b deficiency. Borregaard and Tauber reported two CGD patients whose neutrophils showed a deficiency of FAD and absent cytochrome b in neutrophil fractions rich in specific granules although these patients' PMNs had normal quantities of FAD in fractions containing plasma membrane and cytosol.[21] We determined the FAD content in the particulate fractions of PMNs from 28 patients with CGD. FAD was normal in 14 patients whose PMNs contained normal levels of cytochrome b (Fig 4). CGD patients with PMN cytochrome b deficiency were separated into two groups; significantly reduced FAD (~25% of normal) was observed in four patients, whereas FAD was normal in eight patients (Table 2, Fig 4). The results support a close relationship between cytochrome b deficiency and reduced FAD content but indicate that cytochrome b deficiency with normal FAD also exists.

TCA: A Polymorphic Genetic Marker in Leukemias and Melanoma Cell Lines

By A van Leeuwen, P.I. Schrier, M.J. Giphart, I.A. Noordermeer, D.J. Ruiter, P. Rubinstein, and J.J. van Rood

TCA (T Cell system A) is a di-allelic system of HLA-like antigens encoded by genes located about 15 cM telomeric to HLA-A. In normal individuals, TCA antigens are only expressed on a subpopulation of T cells, the T_G lymphocytes. We now report on the expression of TCA on leukemias and other malignancies. An increased proportion of cells carrying the TCA phenotype was encountered in testing peripheral blood lymphocytes from patients with acute lymphoblastic T-cell leukemia (T-ALL), acute myeloid leukemia (AML), and chronic myeloid leukemia (CML). In contrast, patients with B-cell malignancies such as chronic lymphatic leukemia (CLL) and hairy cell leukemia (HCL) or non-T/non-B common acute lymphoblastic leukemia (common ALL) had normal proportions of TCA-positive lymphocytes. Quantitatively different levels of TCA expression are found on some melanoma cell lines and others are TCA negative. These variations are independent of the expression of HLA Class I antigens by the same cells. The expression of TCA antigens by malignant nonlymphoid cells suggests that this system may code for differentiation markers, important in the biology of neoplastic transformation.

© 1986 by Grune & Stratton, Inc.

WE HAVE recently described a diallelic system of antigens coded by genes that map 15 cM telomeric to HLA-A in chromosome 6.[1,2] These antigens, designated TCA-1 and TCA-2, are comprised of an α-chain (MW $\simeq$ 42.000) and β_2-microglobulin, and are, therefore, homologous of the murine H-2–linked Tla-Qa antigens. The expression of Tla and Qa in malignant cells has been reported to be different from that in normal cells,[3] which suggests the participation of this genetic system in the biology of neoplasia. The identification of TCA antigens by serological methods is complicated by the frequent coexistence of HLA antibodies in the same sera.

We have, therefore, developed an approach by which antibodies against TCA or other possible equivalents of Qa or Tla could be identified.[1,4] Sera were collected from highly immunized individuals (mainly multiparous women) who carried the very frequent HLA-A1, B8, DR3 haplotype. The sera were then tested against a panel of HLA-A1, B8, DR3–homozygous cells that guaranteed that any antibodies reactive with Class I or Class II antigens would not find a target. In this manner, sera containing interesting antibodies were identified and the unwanted antibodies subsequently removed by absorption to permit their use as conventional typing reagents. Such reagents have allowed us to describe four non-HLA antigens belonging to two distinct immunogenetic systems.[2] One, the TCA system, is normally expressed only by the T_G subpopulation of peripheral blood lymphocytes. Since those cells comprise only 10% of peripheral blood lymphocytes, an enrichment procedure had to be used as well.

The discovery of TCA allows us to approach the study of the chromosomal region distal to HLA-A in humans. Data from the murine work suggests that this region may contain additional Class-I-like (or class IV[5]) genes with interesting functional properties.

We have, therefore, investigated the expression of TCA antigens by neoplastic cells. Our results reveal that the proportion of TCA-positive cells is consistently increased in patients with either acute lymphoblastic T cell leukemia (T-ALL) or myeloid malignancies such as acute myeloid leukemia (AML) and chronic myeloid leukemia (CML). TCA, however, is not increased in patients with B cell malignancies, such as chronic lymphatic leukemia (CLL) and hairy cell leukemia (HCL) or non-T/ non-B common acute lymphoblastic leukemia (common ALL). We also found TCA to be expressed by some but not all melanoma cell lines in which it occurs independently of the expression of conventional HLA antigens. One of us[6] has previously described that loss of expression of those antigens by melanoma tumors may be associated with a poor prognosis.

MATERIALS AND METHODS

Antisera Sera, selected as described elsewhere,[1] were absorbed with EBV-transformed B cell lines derived from the respective husbands of the serum donors. This procedure, which eliminates HLA-A, -B, -C, and DR antibodies, had also been described previously.[1]

Normal lymphocytes. T lymphocytes were separated from Ficoll-Isopaque–prepared mononuclear cells by forming sheep red cell rosettes. T_G–enriched suspensions were then isolated using theophylline[4] which dissociates the rosettes formed by non-T_G cells.

Leukemic lymphocytes. Fresh as well as frozen peripheral blood lymphocytes from 62 leukemia patients were tested Ten cases were diagnosed as CLL, five as HCL, nine as common ALL, 16 as AML, nine as CML, two as monocytic leukemia (Mon L), and 11 as T-ALL The Ficoll-Isopaque separated suspension was not fractionated further

Complement-dependent cytotoxicity (CDC) technique. The CDC test was described elsewhere [7] In short, cells were incubated for one hour with one volume of antiserum at 10 °C followed by two hours incubation with five volumes of complement at 20 °C. Ethidium bromide was used as an indicator. Each reaction was scored according to the percentage of cells killed. A negative control was used to define negative and positive reactions. It consists of testing the target cells with platelet-absorbed AB serum plus complement· a positive reaction results in at least twice the percentage of dead cells observed in the AB control. Cytotoxicity scores were calculated

according to the proportion of dead cells and are presented here together with an indication of their variability in the replicate determinations Between 200 and 500 lymphocytes were evaluated for viability in each test

Melanoma cell lines Melanoma cell lines were grown in DMEM supplemented with 10% fetal calf serum and trypsinized from the plastic dishes just before assaying for cytotoxicity with anti-HLA and anti-TCA sera. Mel 2a is a cell line established from an axillary lymph node metastasis from a 43-year-old female patient, passage 400. O-Mell II is a cell line from cells, isolated from pleural exudate of a 45-year-old male patient, passage 40. This patient was treated with DTIC. Mel 57 is a cell line derived from a local skin metastasis from the leg of a female patient that died in 1975 with a superficial spreading melanoma [8] Passage 120. Cell line IGR is established from an inguinal lymph node metastasis from a 30-year-old male patient. The original tumor was amelanotic of epithelial origin [9] Passage 50. CMel 136 is a cell line derived from the metastasis of the axillary lymph node from a 35-year-old male patient who had a primary melanoma of the nipple which had been excised two months earlier. CXCMel is a cultured xenograft of CMel 136 in Balb C nude mice

RESULTS

Leukemia patients. Peripheral blood lymphocytes and blasts from leukemia patients were tested with anti-TCA sera. The expression of TCA on leukemic cells were measured by the complement-dependent cytotoxicity (CDC) reaction of alloantisera and peripheral blood lymphocytes after Ficoll-Isopaque separation. A partial list of results is shown in Table 1. Patients with B cell malignancies (CLL and HCL) and non-T/non-B Common ALL gave similar patterns of cytotoxicity to those observed with unseparated lymphocytes from healthy individuals. In contrast, nonenriched lymphocytes from the 11 patients with T-ALL (three are shown in Table 1) and the two with monocytic leukemia tested to date show a highly increased proportion of TCA positive cells (2 to 8 times the normal level, see Table 1). In the majority of cases of AML and CML (AML 1°, AML 2, AML 3, CML 2, CML 3), a highly increased expression of TCA was also found (Table 1).

The levels of TCA reactivity of AML 1⁺ and CML 1 in nonleukemic phase were similar to the control, but blood collected from one of these patients in a subsequent leukemic phase (AML 1°, Table 1) demonstrated TCA antigens in a high proportion of the mononuclear cells. Two additional cases of reduced expression of TCA in remission of leukemia and their reappearance during leukemic phases have been encountered. We postulate, therefore, that enhanced expression of TCA is associated exclusively with the leukemic phase in patients with T-ALL, Mon L, AML, and CML and not with B cell or common AL leukemias.

It is evident that the levels of reactivity with the negative control serum (AB*) are variable, ranging from 4% to 21%. The use of frozen cells or the increased sensitivity to complement of leukemic cells from those patients may explain these higher negative control values. Especially in the monocytic leukemias and in the T-ALL patients the control values (AB*) are high; however, a clear increase in the percentage

Table 2 Total Number of Leukemia Patients Tested for the Expression of TCA

Diagnosis	Increased Expression	Low Expression
CLL	0	10
Hairy CL	0	5
Common ALL	0	9
AML	11 (leuk phase)	5 (nonleuk phase)
CML	8 (leuk phase)	1 (nonleuk phase)
Mon L	2	0
T-ALL	11	0

Ficoll-Isopaque–isolated lymphocytes were defined as showing "increased expression" when a clear TCA pattern was found, and "low expression" when no TCA antigens were detected, using unseparated lymphocytes.

of positive cells could be observed. Because the reactions were read with an inverted microscope containing phase contrast, it could be demonstrated clearly that the positive reactions were selectively due to lysis of the blast cells in the peripheral blood lymphocyte suspension. Moreover, since the two-color fluorescence technique was used it was also obvious that B cells were not lysed.

The last column of Table 1 gives the TCA phenotypes of the patients with increased TCA antigenic expression. Patients with the three possible TCA phenotypes, ie, both homozygotes and the heterozygote classes, were encountered in the proportions expected from the Hardy-Weinberg equilibrium. Table 2 summarizes the TCA results with leukemic patients obtained to date. All of the leukemia patients showed normal HLA Class I and Class II antigen expression, as expected from previous experience.

Melanoma patients Since non-T cell leukemias, such as AML, also show TCA expression, we were interested in determining whether or not TCA is also expressed by malignancies other than those of hematopoietic origin. Consequently, we tested a number of melanoma cell lines. The expression of HLA in malignant melanoma has been reported to be highly variable[6] and Table 3 shows that four out of six melanoma cell lines do not react with anti-Bw4/Bw6 sera.

Table 3. Expression of HLA-B (Class I) and TCA on Melanoma Cell Lines as Demonstrated by the Reaction Patterns With Different Anti-Bw4, Anti-Bw6, Anti-TCA1, and Anti-TCA2 Sera

Melanoma Cell Lines	Anti–Class I		Anti-TCA	
	Bw4	Bw6	1	2
Mel 2a*	0	0	0	0
0-Mel II*	0	0	0	0
Mel 57	5	5	0	0
IGR	0	5	3	0
CMel 136*	0	0	4	4
CxCMel 136*	0	0	3	2

All melanoma cell lines were tested for HLA antigens using the standard NIH technique.[14] For TCA typing the CDC technique was used as described in Materials and Methods The scores used from 0 to 5 indicate: 0 = 0–10% dead cells, 1 = 11–20%, 2 = 21–30%, 3 = 31–50%, 4 = 51–80%, and 5 = 81–100%.

Bw4 and Bw6 are representative for the HLA-B locus All normal peripheral blood lymphocytes react at least with one of the two anti-Bw4 or anti-Bw6 sera.

*These cell lines are also unreactive with other HLA-A,-B, or-C antisera.

Those cell lines were also unreactive with other HLA-A, -B, or -C antisera These negative serological results were further confirmed by a highly reduced transcription of Class I MHC genes as detected on Northern blots (P.I. Schrier, unpublished observations). Of these HLA-A, -B, -C negative lines, CMel 136 and CXCMel 136 show high expression of TCA*1 and TCA*2. Two other cell lines (IGR and Mel 57) that have easily detectable Class I HLA-A, -B, -C (Table 3) differ in their TCA status. One line does not express TCA, while another is positive for TCA*1. The cell lines Mel 2a and O-Mel II neither express Class I nor TCA.

The reciprocal expression of TCA and HLA on CMel 136 and, for instance, Mel 57, stresses that Class I HLA-A, -B, -C, and TCA are clearly separate determinants on the membrane of the tumor cells. However, they are not mutually exclusive because cell line IGR, which has a high Class I expression, also expresses TCA.

DISCUSSION

The presence of TCA antigens in T cell leukemias might be expected from their normal T_G counterparts. It is, however, surprising that this system is expressed by all T cell leukemias studied, which suggest that either at least some normally TCA-negative cells may become positive as a result of neoplastic transformation or that the increased TCA expression is the result of a clonal expansion of TCA-positive cells in the peripheral blood. A similar finding with several myelocytic leukemias supports these suggestions. The association of TCA expression with neoplasia is not restricted to cells of the hematopoietic system, since at least some melanoma cell lines display high levels of TCA antigen expression. These cell lines, however, are rather heterogeneous with respect to the expression of HLA and/or TCA antigens. This is not a result of the well-known HLA variability in melanomas since TCA+, HLA (−); TCA(−), HLA+; TCA+, HLA+; and TCA (−), HLA(−) cell lines have been identified.

We can only speculate about the role of the increased expression of TCA on tumor cells. Malignant melanoma is a disease that elicits antibody to tumor-associated antigens and autologous cytotoxicity in some individuals[10] and might, therefore, be considered as a particularly immunoreactive human tumor. The low expression of Class I MHC molecules on the membrane may interfere with Class I–restricted recognition of tumor cells by cytotoxic T cells, thus allowing the tumor cells to evade the host's immune defense Examples of such a mechanism in experimental animal models have been described.[11–13] In this report we have shown that, in some instances, the decreased expression of Class I is associated with the appearance of new Class I–like determinants, such as TCA.

It remains to be demonstrated whether this also interferes with CTL recognition.

In this context, it is probably relevant that especially invasive melanoma metastases display low expression of HLA-A, -B, -C,[6] and accorded unusually low levels of lymphocytic infiltration in the patients. Accurate quantitation of the expression of TCA in these tissues is presently under investigation, to see whether TCA is also highly expressed in these tumors as has been found on the leukemic blasts. The results so far suggest that two mechanisms are involved in malignancies: (1) a decreased Class I expression interfering with lymphocytotoxicity, and (2) an increased TCA expression (along with any pattern of HLA expression).

A thorough characterization of TCA antigens and their regulation in tumor cells is, therefore, necessary and may provide a clue to their role in human malignancies.

ACKNOWLEDGMENT

We wish to thank Drs J. Jansen and M van 't Veer for the leukemic lymphocytes, Dr J.E. de Vries for providing the melanoma cell lines Mel 2a and O-Mel II, Mr M R.M. van den Brink for subcloning these lines, G. de Groot and S. van Bree for expert technical assistance, Dr J. d'Amaro for useful advice, and P.R. van der Poel and T van Westerop for typing the manuscript.

Effect of Activated Lymphocytes on the Regulation of Hematopoiesis: Enhancement and Suppression of In Vitro BFU-E Growth by T Cells Stimulated by Autologous Non-T Cells

By Mine Harada, Shinji Nakao, Kunio Kondo, Kazuaki Odaka, Mikio Ueda, Shintaro Shiobara, Kosei Matsue, Takao Mori, and Tamotsu Matsuda

Autologous mixed lymphocyte culture (AMLR) is an immunologic response with memory and specificity and plays a role in immune regulation. Effects of T cells activated by AMLR were studied in the regulation of in vitro erythropoiesis. AMLR-activated T cells were cocultured with autologous non-T, nonphagocytic peripheral blood mononuclear cells for assaying erythroid progenitor cells (BFU-E). T cells activated for 3 days in AMLR showed significant enhancement of in vitro colony growth by BFU-E. In contrast, activated T cells from day 7 AMLR caused significant suppression of BFU-E growth. Both enhancing and suppressing activities of AMLR-activated T cells were mediated by an Ia-positive and radiosensitive population within the OKT4$^+$ subset. These observations suggest that AMLR-activated T cells may play a role in the immune-mediated regulation of in vitro erythropoiesis. It is also suggested that heterogeneous T-cell subsets may exert regulatory functions in the regulation of in vitro hematopoiesis.

T CELLS play an important role in the regulation of hematopoiesis.[1-5] Recently we have shown that T cells activated in vitro by concanavalin A or alloantigens in mixed lymphocyte reaction (MLR) could suppress in vitro colony formation by erythroid and/or myeloid progenitor cells.[6,7] Similar data have been reported by several investigators.[8-11] Concanavalin A and alloantigen stimulation is well known for its capacity to induce suppressor cells that operate in immune systems, such as in vitro immunoglobulin synthesis and MLR.[12-14] Another population of T cells that may affect the immune regulation is autoreactive T cells, which will proliferate in response to stimulation by autologous non-T cells in autologous MLR (AMLR).[15,16] AMRL is an immunologic response with memory and specificity[16,17] and T cells activated in AMLR have some immunoregulatory functions.[18] We investigated the effects of AMLR-activated T cells on immature erythroid progenitor cells (erythroid burst-forming unit, BFU-E) and found that these activated T cells exerted dual regulatory functions for in vitro colony growth by peripheral blood BFU-E.

MATERIALS AND METHODS

Preparation of T cells and non-T cells. Heparinized peripheral blood from normal volunteers was diluted with an equal volume of RPMI 1640 medium (GIBCO, Grand Island, NY), layered over a Ficoll-Hypaque density gradient, and centrifuged at 400 × G for 30 minutes. Peripheral blood mononuclear cells (PBMC) were obtained from the interface and washed twice with RPMI 1640. Then T cells and non-T cells were separated from PBMC by using the rosette sedimentation technique.[19] This procedure was repeated twice. T cells obtained in this way were >98% positive for T3 as determined by OKT3 monoclonal antibody (Ortho Pharmaceutical Corp, Raritan, NJ) staining on a FACS analyzer (Becton Dickinson, Mountain View, Calif) while non-T cells contained ≤5% OKT3-positive cells.

Isolation of T-cell subsets An OKT4- or OKT8-positive cell fraction was isolated by negative selection. T cells (1×10^7/mL) were mixed with 50 μg/mL of OKT4 or OKT8 monoclonal antibody (Ortho Pharmaceutical Corp) and incubated at 4 °C for 30 minutes The mixture was further incubated with an equal volume of 1:3 diluted rabbit serum (Lot 029957A, Behringwerke AG, Marburg, West Germany) as a source of complement at 37 °C for 45 minutes. This monoclonal antibody plus complement treatment was repeated Treated cells were washed once and adjusted to an appropriate number of viable cells Complement-mediated cell lysis was confirmed by trypan blue dye exclusion and cytofluorography. Eighty-eight percent to 95% killing of each T-cell subset occurred following treatment with the corresponding antibody and complement. OKT8-treated T cells were enriched for OKT4-positive cells and OKT4-treated T cells for OKT8-positive cells. These isolated T-cell subsets were referred to OKT4$^+$ and OKT8$^+$ cells, respectively, and were used as responder cells in AMLR.

Preparation of non-T, nonphagocytic PBMC. For the separation of nonphagocytic cells, 5% silica particle solution (KAC-2, Japan Immunoresearch Laboratory, Takasaki, Japan) was added to heparinized peripheral blood at an 1:9 ratio and incubated at 37°C for 60 minutes The mixture was then layered over a Ficoll-Hypaque density gradient and centrifuged at 400 × G for 30 minutes Furthermore, T cells were removed from this nonphagocytic cell fraction by using the rosette sedimentation technique.[19] The resulting non-T, nonphagocytic PBMC were approximately 10% positive for nonspecific esterase staining and contained ≤9% OKT3-positive and ≤15% Ia-positive cells, respectively. These cells were cryopreserved[20] until the use for assaying BFU-E.

Autologous mixed lymphocyte reaction (AMLR). A bulk AMLR was performed by culturing 5×10^6 T cells with 5×10^6 irradiated (20Gy) autologous non-T cells in 10 mL of RPMI (GIBCO, Grand Island, NY) supplemented with 15% pooled human serum at 37°C in a humid 5% CO_2 atmosphere.[21] For unstimulated cultures, 5×10^6 irradiated autologous T cells were added instead of non-T cells. In some experiments, OKT4$^+$ or OKT8$^+$ cells were used as responder cells Responder cells were harvested on days 3, 7, and 12 of AMLR and T cells were separated again by using the rosette sedimentation technique.[19] These responder T cells were washed three times with RPMI 1640 before coculturing with non-T, nonphagocytic autologous PBMC for BFU-E assays

Treatment with OKIal monoclonal antibody and radiation In some experiments, responder T cells harvested from AMLR (1×10^7/mL) were treated with an OKIal monoclonal antibody (50

T cells stimulated by autologous T cells or non-T cells were harvested from day 3, 7, or 12 AMLR 1 × 10^5 AMLR-activated T cells were cocultured with 2 × 10^5 autologous non-T, non-phagocytic PBMC for assaying BFU-E. Each value represents M ± SEM in 5 experiments

*T/Tx and T/non-Tx indicate the combination of T cells and irradiated T cells or non-T cells in AMLR, respectively.

†Statistically significant at $P < 0\ 025$ level.

‡Percent of control BFU-E–derived colonies was calculated as follows (No of BFU-E colonies in coculture with AMLR-activated T cells/No. of BFU-E colonies in culture with no added T cells) × 100.

μg/mL; Ortho Pharmaceutical Corp) and complement before cocultures as described above. Treated cells were washed once and resuspended in the initial volume. Radiation treatment was performed by 20 Gy irradiation of the AMLR-activated T cells.

BFU-E assays. BFU-E were assayed by using the technique of Iscove in methylcellulose method[22] with a minor modification. Non-T, nonphagocytic PBMC (2 × 10^5/plate) with or without AMLR-activated T cells were cultured in 0 9% mehtylcellulose in Iscove's modified Dulbecco's medium (Sigma Chemical Co, St Louis, Mo) supplemented with 30% fetal calf serum, 1 unit of erythropoietin (Connaught Step III, lots 3083-1, 3084-1), and 5% PHA-stimulated leukocyte-conditioned medium[23] as a source of burst-promoting activity Cultures were performed in triplicate in 35 mm plastic dishes (Falcon #3010, Oxnard, Calif) and maintained at 37 °C in 5% CO_2 atmosphere with 100% humidity. On day 14 colonies with more than 100 hemoglobinized cells or clusters of three or more subcolonies were scored as BFU-E. Colonies were confirmed as erythroid by staining for hemoglobin with benzidine and by May-Giemsa staining.

Statistical analysis. The Student *t* test was employed for statistical analysis of the data obtained in the present study.

RESULTS

Table 1 shows effects of AMLR-activated T cells on in vitro BFU-E growth. When T cells stimulated by irradiated autologous T cells (T/Tx) were added to autologous non-T, nonphagocytic PBMC for BFU-E assays, they did not affect BFU-E growth. T cells activated by irradiated autologous non-T cells (T/non-Tx) increased BFU-E growth at a significant level ($P < 0.025$) when they were harvested on day 3 of AMLR. In contrast, T cells activated by autologous non-T cells for 7 or 12 days in AMLR showed a significant suppression of BFU-E growth ($P < 0.025$) A dose-dependent enhancement or suppression of BFU-E growth was observed. In a representative experiment, percentages of control BFU-E–derived colonies were 117, 160, and 167 with the addition of 0.5 × 10^5, 1.0 × 10^5, and 2.0 × 10^5 day 3 AMLR-activated T cells, respectively, while they were 62, 54, and 27 with the addition of 0.5 × 10^5, 1.0 × 10^5, and 2.0 × 10^5 day 7 AMLR-activated T cells, respectively.

Table 2 provides the data to determine whether AMLR-activated T cells will affect allogeneic BFU-E growth or not. Activated T cells harvested from day 3 AMLR showed a significant increase ($P < 0.05$) of not only autologous but also allogeneic BFU-E growth when they were added to BFU-E assays. However, activated T cells harvested from day 7 AMLR suppressed only autologous BFU-E growth ($P < 0.05$). Allogeneic BFU-E growth was unaffected by adding day 7 AMLR-activated T cells to BFU-E assays

Next, effects of AMLR-activated OKT4$^+$ or OKT8$^+$ cells on BFU-E growth were studied. As shown in Fig 1, OKT4$^+$ cells activated by autologous non-T cells exerted regulatory functions while AMLR-activated OKT8$^+$ cells did not. Activated OKT4$^+$ cells harvested from day 3 AMLR increased BFU-E growth in comparison with the unactivated control ($P < 0.025$). This increase in BFU-E growth was comparable to that exerted by day 3 AMLR-activated T cells. In contrast, activated OKT4$^+$ cells harvested from day 7 AMLR showed a significant suppression of BFU-E growth ($P < 0.025$), which was almost identical to that exerted by day 7 AMLR-activated T cells.

AMLR-activated T cells expressing regulatory functions for BFU-E growth were studied for the presence of Ia antigens and radiosensitivity. When AMLR-activated T

cells were treated with an OKIal monoclonal antibody and complement before cocultures, both BFU-E enhancing and suppressing activities were completely abolished (Fig 2). Enhancement and suppression of BFU-E growth were unaffected by addition of AMLR-activated T cells treated with complement alone. Similarly, both of the two opposing functions were completely abolished when these activated T cells were 20 Gy irradiated before cocultures (Fig 3).

When T cells were stimulated by allogeneic non-T cells instead of autologous ones in a conventional one-way MLR, T cells activated by alloantigens for 3 or 7 days in MLR had no effects on in vitro growth of BFU-E as shown in Fig 4. On

the other hand, T cells activated by AMLR expressed dual functions for BFU-E growth depending on the culture period of AMLR.

DISCUSSION

The present study demonstrates that T cells activated by autologous non-T cells in AMLR exert both enhancing and suppressing activities in the regulation of in vitro erythropoiesis; those from day 3 AMLR enhanced and those from days 7–12 AMLR suppressed BFU-E growth. Both of these regulatory functions were mediated by an Ia-positive and radiosensitive population within the AMLR-activated OKT4$^+$ cells. Furthermore, activated T cells harvested at an early stage of AMLR enhanced both autologous and allogeneic BFU-E growth; those at a late stage of AMLR suppressed only autologous BFU-E. These observations suggest that in vitro differentiation and proliferation of erythroid progenitor cells may be regulated at least partly by autoreactive T cells.

Several investigators have shown that in vitro growth of erythroid progenitor cells can be enhanced by coculturing them with normal or unactivated T cells and T-cell subsets.[1-3] Similarly, recent studies indicate that unactivated T-cell subsets, both OKT4$^+$ and OKT8$^+$ cells, could stimulate in vitro growth of BFU-E without collaboration between them.[24,25] In the present study, only OKT4-positive T cells activated by 3-day AMLR increased in vitro growth of peripheral blood BFU-E. These AMLR-induced BFU-E–enhancing T cells were found to be Ia-positive and radiosensitive. Therefore, this AMLR-activated T-cell subset is probably different from T-cell subsets affecting BFU-E growth reported by others.[2,3,23,24] Mechanisms by which AMLR-activated T cells exerted the BFU-E growth-enhancing activity are unknown. One possible explanation is that they are capable of producing burst-promoting activities, as described by Wisniewski et al.[25]

The present study provides evidence suggesting that AMLR-activated T cells may exert dual functions in the regulation of BFU-E growth. Torok-Storb et al[2,26] have also demonstrated that normal T cells affecting BFU-E growth can be divided into at least two functionally different subsets defined by monoclonal antibodies and that a population of Ia-positive T cells limits BFU-E growth. Similarly, Mangan et al[3] reported the presence of BFU-E–regulating T-cell subpopulations defined by Fc receptors and monoclonal antibodies. However, these T-cell subsets with regulatory functions were not activated in vitro. Our data show that in vitro colony formation by BFU-E was affected by the two functionally different T-cell subsets. Both of them were Ia-positive and radiosensitive within the OKT4$^+$ phenotype but they were harvested at different stages of AMLR for activation. From our data, however, it is not determined whether these T-cell subsets with opposing functions were identical or not before activation of AMLR; one possibility is that there may exist two distinct subpopulations before activation, and another is that the same T-cell population may be induced to express the two opposing functions successively upon activation in AMLR.

In contrast to nonspecific or genetically unrestricted stimulation of BFU-E growth by unactivated or activated T cells in our study and others,[1-3,24,25] T cells activated by 7-day AMLR suppressed only autologous, but not allogeneic BFU-E. This suggests a possible presence of genetic restriction in expressing a regulatory function by AMLR-induced BFU-E–suppressor T cells. Genetic restriction of T cells suppressing erythroid colony growth has been reported by Torok-Storb and Hansen[26] and Lipton et al.[27] These erythroid suppressor T cells were Ia-positive, although they were not activated in vitro. Data from the former study[26] suggest that a subset of Ia-positive T cells may suppress BFU-E growth by limiting a monocyte-dependent T-cell stimulation activity for BFU-E growth through HLA-DR antigen recognition.[28] This is unlikely in our study since OKIal plus complement treatment of AMLR-activated T cells abolished suppression of BFU-E growth but did not result in increased stimulation of BFU-E growth. Since activated T cells are able to generate a variety of lymphokines,[11,29,30] and interferons can inhibit proliferation of hematopoietic progenitor cells,[11,31] it is possible that suppression of BFU-E growth may be mediated by interferon(s) produced by activated OKT4$^+$ cells from day 7 AMLR. Recently we have shown that concanavalin-A–stimulated T cells can suppress in vitro growth of erythroid and myeloid progenitor cells[6]; they were OKT8-positive but Ia-negative. Thus, our data together with others indicate that T cells involved in the regulation of in vitro erythropoiesis are heterogenous in their immunologic phenotype.

AMLR has been shown to be abnormal or defective in a variety of diseases characterized by disturbed immune regulations.[18,32] Recently Kotani et al[33] have demonstrated that OKT4$^+$ cells activated for 3 days in AMLR exert helper activity for pokeweed mitogen-induced immunoglobulin synthesis while those from day 7 AMLR express suppressor activity. These observations suggest that AMLR may play an important role in maintaining normal immune regulation. In this regard, our data indicate a possibility that AMLR may be actively involved in the immune-mediated regulation of in vitro erythropoiesis; dual functions successively exerted by AMLR-activated T cells could provide a "regulatory circuit" in which AMLR-induced BFU-E–suppressor T cells may exert a "feedback suppression" for BFU-E growth stimulated by AMLR-induced BFU-E–enhancing T cells.

Controlled Trial of Desmopressin in Liver Cirrhosis and Other Conditions Associated With a Prolonged Bleeding Time

By Pier Mannuccio Mannucci, Vicente Vicente, Luciana Vianello, Marco Cattaneo, Ignacio Alberca, Maria Piera Coccato, Elena Faioni, and Daniela Mari

The synthetic vasopressin derivative desmopressin (DDAVP) shortens a prolonged bleeding time (BT) in patients with uremia, congenital platelet dysfunction, and von Willebrand disease. To establish the limits of the clinical usefulness of DDAVP, a controlled randomized study was carried out in 53 patients and ten volunteers with different conditions that have in common a prolonged BT. DDAVP significantly shortened the BT in 21 cirrhotics ($P < .01$), in eight patients with unclassified prolonged BT ($P < .05$) and in ten volunteers taking the antiplatelet drugs aspirin ($P < .05$) and ticlopidine. The BT changes were not statistically significant in 15 patients with severe thrombocytopenia nor in nine with congenital platelet dysfunction, even though a few patients with storage pool deficiency responded with a marked BT shortening. Our findings indicate that DDAVP might be given when biopsies or other surgical procedures must be carried out in patients with prolonged BT. However, the compound is often ineffective in patients with thrombocytopenia or congenital platelet dysfunction.

RECENT STUDIES have shown that the synthetic vasopressin derivative desmopressin (DDAVP) shortens the prolonged bleeding times (BT) associated with a variety of clinical disorders of primary hemostasis.[1-4] In von Willebrand disease, the most common congenital cause of prolonged BT, the effectiveness of DDAVP is clearly explained by the fact that the prolonged BT is due to low or abnormal plasma von Willebrand factor (vWF), the most important determinant of platelet adhesion to the damaged vessel wall.[5] By releasing autologous vWF from storage sites (possibly the endothelial cells), DDAVP transiently normalizes vWF levels and shortens the BT, at least in patients with vWF that is functionally normal.[1] However, DDAVP also shortens the BT in such conditions as uremia[2,3] and congenital and acquired platelet dysfunctions,[4] in which no quantitative or qualitative vWF abnormality has been convincingly demonstrated. These observations, together with a recent in vitro study demonstrating a local hemostatic effect of the drug on the vessel wall,[6] led us to postulate that DDAVP might have broader clinical usefulness as a primary hemostatic agent in patients with prolonged BT due to causes other than low or dysfunctional vWF. To establish the limits of the clinical usefulness of DDAVP, we have carried out a controlled study in 53 patients with different clinical conditions that have a prolonged BT in common, and in ten volunteers taking the antiplatelet drugs aspirin or ticlopidine.

MATERIALS AND METHODS

Patients. Fifty-three patients (25 men and 28 women, with a median age of 37 years; range, 15 to 65) seen at the A. Bianchi Bonomi Hemophilia and Thrombosis Center in Milan, Italy, or at the Department of Hematology in Salamanca, Spain, were admitted to the study on the basis of a BT of ten minutes or longer when measured before the first experimental treatment (see below). Even though the upper normal BT limit is seven minutes at both centers, an admission limit of ten minutes was chosen because we consider this value to be the clinical threshold between normal and abnormal hemostasis. Of the 53 patients admitted to the study, 21 had alcoholic or postnecrotic liver cirrhosis, diagnosed by liver tests and biopsy. Their platelet counts were normal or moderately low (median, 106 × 10^9/L; range, 45 to 286). Fifteen patients had severe thrombocytopenia (median platelet count, 13 × 10^9/L; range, 1 to 53), due to increased platelet destruction by autoantibodies in five cases and due to decreased bone marrow production in ten cases (seven had aplasia, one familial thrombocytopenia, one myeloma, one chronic lymphocytic leukemia). Nine patients belonging to different kindreds had congenital platelet dysfunction, diagnosed as delta storage pool deficiency in seven and Glanzmann thrombasthenia in two cases, according to previously described criteria.[7,8] Finally, eight patients had prolonged BT associated with lifelong histories of bleeding but with normal platelet counts, no laboratory evidence of von Willebrand's disease, no defect in platelet aggregation or secretion, no storage pool deficiency, nor any underlying condition known to be associated with a prolonged BT. These unexplained prolonged BT might be due to vascular defects or to as yet unidentified platelet dysfunctions. We have called this patient group "unclassified prolonged BT." None of the patients had taken aspirin or other drugs that affect platelet behavior for at least ten days before the study.

We also studied six volunteers who had borderline or slightly prolonged BT due to the ingestion of 500 mg aspirin two hours before the study, and four volunteers who had very prolonged BT because they had taken a daily dose (500 mg) of the antiplatelet drug ticlopidine for six days before the study. Ticlopidine is a potent antiplatelet agent, available in Europe and presently under clinical trials in the United States and in Canada, which markedly prolongs the BT through a presently unknown mechanism.[9] All the patients and volunteers were aware of the nature and the purpose of the study, and all gave informed consent according to the Declaration of Helsinki.

Design of the study. Patients and volunteers were randomly assigned to a single infusion of DDAVP (Valeas, Milan, Italy) or of saline, and each of them was crossed over from one treatment to the other after 20 days. After a rest period of at least 30 minutes, 0.3 μg of DDAVP per kilogram body weight was added to 50 mL of physiological saline and infused over a period of 30 minutes; physiological saline alone was infused in the same way. The study

could not be performed on a double-blind basis because DDAVP infusion can be detected by an accompanying mild facial flushing.

Blood samples were collected and plasma prepared as previously described.[1]

Laboratory methods. The tests were performed in Milan and Salamanca with the same reagents, methods, and standards, except that vWF multimeric analysis was done in Milan on plasma samples kept frozen at −70 °C and transported in dry ice. All tests were carried out on blood drawn before the infusion of DDAVP or saline (time 0), immediately after the infusion (time 30), and four hours after the infusion had been started (time 240).

Bleeding times were obtained with the Simplate II device (General Diagnostics, Milan, Italy). Results were expressed as the average BT from the two vertical incisions. In both laboratories, the range of normal with this method was three to seven minutes. Platelets were counted by phase-contrast microscopy. The prothrombin time (PT) was determined by using the Manchester Comparative Reagent (overseas version, Laboratori Baldacci, Pisa, Italy), and the activated partial thromboplastin time (APTT), with a commercial reagent (Automated PTT, General Diagnostics). Values of both the coagulation screening tests were expressed as ratios of patient to pooled normal plasma (obtained from 15 healthy women and 15 healthy men). Factor VIII (FVIII) was assayed by a one-stage clotting method based on the APTT.[1,3] vWF antigen (vWF:Ag) was assayed by quantitative immunoelectrophoresis, using a commercial monospecific antiserum (Istituto Behring, Scopitto, Aquila).[1,3] Ristocetin cofactor (RiCof) was assayed with formalin-fixed platelets.[1,3] FVIII, vWF:Ag, and RiCof were expressed in units per deciliter, with reference to pooled normal plasma calibrated against the First International Plasma Standard for Factor VIII-related Activities (National Institute for Biological Standards, London). vWF multimers were analyzed by agarose electrophoresis in the presence of sodium dodecyl sulfate (SDS), as previously described.[1]

Statistical analysis. The BT values were not normally distributed, and there were BT that did not stop after 30 minutes and were recorded as longer than 30 minutes. Hence BT values before and after DDAVP or placebo were expressed as medians and ranges. The other measurements were normally distributed, and thus were expressed as means ± SD. Correlation coefficients were calculated either by the Spearman *rho* test or as linear correlation coefficients (*r*).

RESULTS

An overall picture of the BT (given as medians and ranges) before and after DDAVP or saline in the patient and volunteer groups is given in Table 1. The two median BT obtained before either treatment (time 0) did not differ significantly in any of the groups.

In patients with liver cirrhosis, the prolongation of the baseline BT was unrelated to the platelet count (Fig 1) (no platelet function tests were performed). At 30 and 240 minutes after DDAVP, the median BT was significantly shorter than at time 0 ($P < .01$, Table 1). In nine of 21 patients at time 30 and in two at time 240, the BT had become shorter than ten minutes, the limit for admission to the study. Responses or non-responses to DDAVP occurred irrespective of the baseline platelet count. After saline, the median BT had not changed significantly at time 30 and at time 240 (Table 1). The BT shortened to less than ten minutes in two patients at time 30 and in five at time 240 (Fig 1). In patients with unclassified prolonged BT, the median BT became significantly shorter after DDAVP ($P < .05$ Table 1); in four of eight patients BT became shorter than ten minutes at time 30 and in three at time 240, but in none after saline (Fig 2).

In patients with thrombocytopenia, there was no significant change in the BT after either saline or DDAVP (Table 1), and the BT was shortened to less than ten minutes in only one case after saline. In the two patients with Glanzmann thrombasthenia, the baseline BT was longer than 30 minutes and remained so at all times after DDAVP or saline. In the seven patients with congenital storage pool deficiency, the median BT did not significantly change after DDAVP or saline (Table 1). After DDAVP, the BT became shorter than ten minutes in two patients at time 30 and in one at time 240, but in none after saline (Fig 3).

Table 1. Bleeding Times Before and After DDAVP or Saline Infusion in Patients With Prolonged Bleeding Times

	DDAVP			Saline		
Group	Time 0 (Before Infusion)	Time 30 (30 min After Infusion)	Time 240 (4 h After Infusion)	Time 0 (Before Infusion)	Time 30 (30 min After Infusion)	Time 240 (4 h After Infusion)
Liver cirrhosis (n = 21)	16 (10-30)	12** (6-20)	13** (5-22)	15 (9-30)	14 (8-25)	14 (7-29)
Thrombocytopenia (n = 15)	>30 (17->30)	>30 (12->30)	>30 (11->30)	>30 (12->30)	>30 (10->30)	>30 (8->30)
Storage pool deficiency (n = 7)	19 (11->30)	11 (7->30)	24 (8->30)	25 (11->30)	30 (10->30)	24 (11->30)
Unclassified prolonged bleeding time (n = 8)	17 (10->30)	11* (7->30)	12* (7->30)	16 (10->30)	16 (10->30)	15 (10->30)
Aspirin takers (n = 6)	8 (7-10)	6** (5-8)	6** (5-7)	8 (7-9)	7 (5-9)	8 (7-10)
Ticlopidine takers (n = 4)	24 (14->30)	8 (6-9)	19 (9-19)	13 (12->30)	17 (14-21)	15 (11-22)

Figures indicate median values and, in parentheses, ranges. Asterisks indicate significance of difference between post-DDAVP or -saline values and baseline values (*$P < .05$, **$P < .01$). Significance was not evaluated for the ticlopidine group because of the small number of patients.

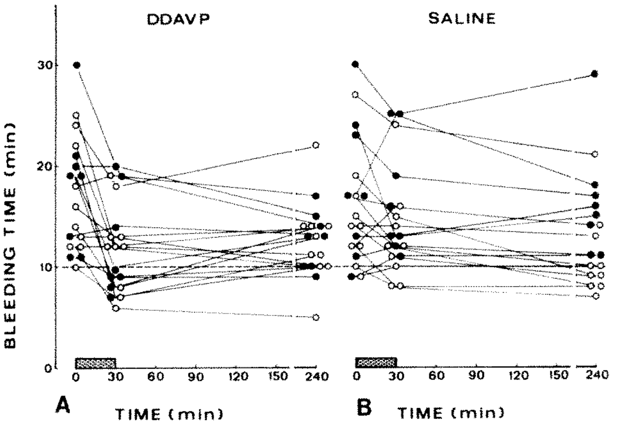

Fig 1. **Changes in bleeding times before (time 0), immediately after (time 30), and 4 hours after (time 240) infusion of DDAVP (left panel) or saline (right panel) in 21 patients with liver cirrhosis. Patients with baseline platelet counts higher than 100 × 10^9/L are indicated by open circles; patients with platelet counts lower than 100 × 10^9/L, by solid circles. The dashed horizontal line indicates a bleeding time of 10 minutes, the value for admission to the trial.**

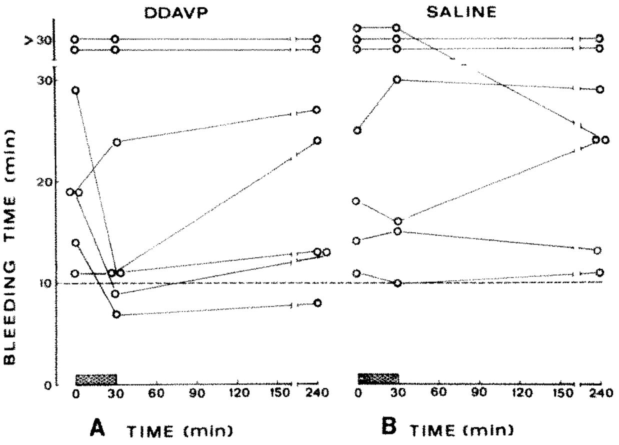

Fig 3. **Changes in bleeding times in seven patients with delta storage pool deficiency.**

In the six volunteers who took aspirin the median BT was significantly shortened at times 30 and 240 after DDAVP ($P < 0.05$) but not after saline (Table 1 and Fig 4). Facial flushing occurred in all cases after DDAVP, whether or not they had taken aspirin. In all four volunteers who took ticlopidine, whose baseline BT were longer than those taking aspirin (Fig 4), the BT had shortened to less than ten minutes at time 30 after DDAVP but had returned to the prolonged values in three at time 240. At no time after saline did the BT shorten to ten minutes or less. Flushing occurred in all cases after DDAVP, whether or not they had taken ticlopidine. These data were not statistically analyzed because of the small number of patients.

After DDAVP or saline, all measurements other than the BT behaved in the same way in each patient or volunteer group. Hence the values for all groups were pooled and analyzed together (Table 2). After DDAVP, there were significant increases in FVIII, vWF:Ag, RiCof ($P < .001$) at times 30 and 240; shortening of the APTT, expressed by a lower ratio ($P < .001$), at times 30 and 240; slight prolongation of the PT expressed by a higher ratio ($P < .01$) at times 30 and 240; and no significant change in the platelet counts. No significant change in any of these was seen after saline. Correlations between the DDAVP-induced changes (differences between pretreatment and posttreatment values) in BT and in other measurements were calculated both for each patient group and for all the groups considered as a whole. No significant correlations were found (data not shown).

The multimeric structure of vWF before and after DDAVP was studied in at least two patients in each group, comparing, when available, one patient in whom the BT became shorter than ten minutes and another in whom it did not. Before DDAVP, the multimeric structure in the patients' plasma was no different from that observed in normal plasma. After DDAVP, larger vWF multimers than those present in pretreatment plasma appeared at time 30 in all patients, whether or not the BT became shorter (Fig 5). There were no changes in the multimeric structure when the patients were treated with saline.

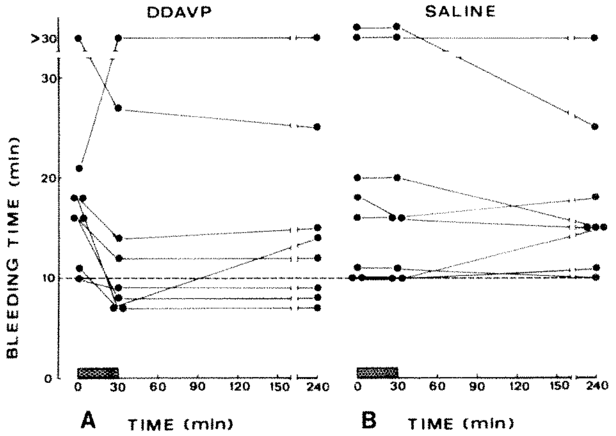

Fig 2. **Changes in bleeding times in eight patients with unclassified prolonged bleeding time.**

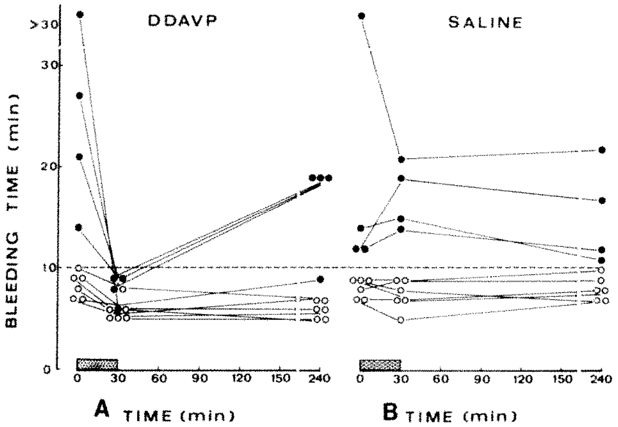

Fig 4. **Changes in bleeding times in six volunteers taking 500 mg aspirin (open circles) and in four volunteers taking 500 mg ticlopidine (solid circles).**

Table 2. Laboratory Measurements Before and After DDAVP or Saline Infusion

	DDAVP			Saline		
	Time 0 (Before Infusion)	Time 30 (30 min After Infusion)	Time 240 (4 h After Infusion)	Time 0 (Before Infusion)	Time 30 (30 min After Infusion)	Time 240 (4 h After Infusion)
vWF:Ag (U/dL)	252 ± 137	291 ± 112***	339 ± 126***	247 ± 129	247 ± 123	249 ± 126

FVIII (U/dL)	151 ± 59	255 ± 69***	310 ± 140***	146 ± 62	143 ± 60	147 ± 58
PT ratio	1.10 ± 0.14	1.13 ± 0.15**	1.13 ± 0.15**	1.09 ± 0.12	1.10 ± 0.12	1.09 ± 0.12
APTT ratio	1.11 ± 0.25	1.02 ± 0.26***	1.00 ± 0.25***	1.11 ± 0.25	1.12 ± 0.26	1.10 ± 0.24
Platelet count ($\times 10^9$/L)	143 ± 122	138 ± 117	140 ± 129	143 ± 116	140 ± 114	152 ± 122

Figures indicate means ± SD. Asterisks indicate significance of differences between post-DDAVP or -saline values and baseline values: $^{**}P < .01$; $^{***}P < .001$ (*t* test for paired samples).

DISCUSSION

The purpose of this controlled study was to see whether or not DDAVP is effective in a number of clinical situations that all have prolonged BT, the best available laboratory indication of abnormal primary hemostasis. The most significant finding was that after DDAVP, the BT became less than ten minutes in about half of the cirrhotic patients. This is the value we consider the upper clinical threshold for normal primary hemostasis. DDAVP was also effective in patients with unclassified prolonged BT and in volunteers taking the antiplatelet drugs aspirin and ticlopidine, whereas the shortening of the BT was not significant in severe thrombocytopenia or in congenital platelet dysfunction, even though three of seven patients with congenital storage pool deficiency responded to DDAVP with a marked BT shortening.

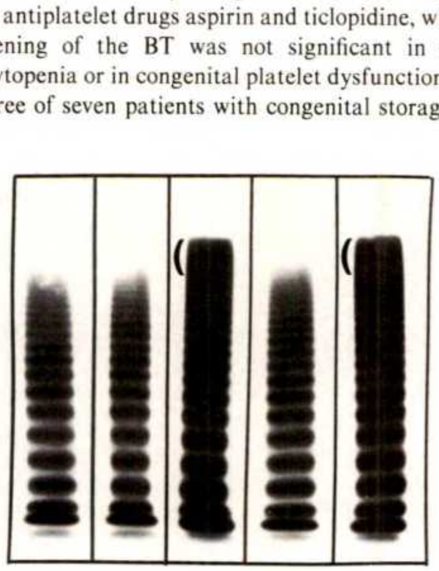

Fig 5. Autoradiograph pattern of plasma vWF electrophoresed in 1.4% high-gelling temperature agarose in the presence of SDS and detected by ^{125}I-labeled affinity-purified antibody. The arrow indicates the origin of the running gel and the anode is at the bottom of the gel. From left to right: normal plasma; plasma from a patient with liver cirrhosis before (bleeding time: 21 minutes) and 30 minutes after (bleeding time: 9 minutes) DDAVP; plasma from another patient with liver cirrhosis before (bleeding time: 20 minutes) and 30 minutes after (bleeding time: 20 minutes) DDAVP. The brackets indicate the large vWF multimers that appear in both plasma after DDAVP.

Why the BT is prolonged in cirrhotics is not completely understood.[10,11] Mild or moderately severe thrombocytopenia is usually present in cirrhosis and was also found in our patients, but their platelet counts were not negatively correlated with their BT. An abnormal vWF is also unlikely because patients had normal or high baseline levels of vWF:Ag and RiCof and the multimeric structure of vWF in their plasma did not differ from that of healthy subjects. Notwithstanding the present uncertainty about the causes of prolonged BT in cirrhotics, the shortening of the BT induced in about half of our patients by DDAVP indicates that this drug might be given when liver biopsies or other surgical procedures would be otherwise contraindicated by a prolonged BT. It must be emphasized, however, that the hemostatic derangement of liver disease is complex, and that the modest and short-lived shortening of the BT seen in most of the responders may not be sufficient to significantly reduce the clinical risk of hemorrhage. The APTT shortened after DDAVP but, at variance with others,[12] we have seen no shortening of the prothrombin time. Hence the hemostatic derangement of liver disease is not completely corrected by DDAVP, and only clinical experience will establish the hemostatic efficacy of the compound.

DDAVP also shortened the prolonged BT induced by the antiplatelet drugs ticlopidine and aspirin, the latter observation being in agreement with that made by Kobrinsky et al[4] in their study of two aspirin-treated patients. It also was useful in the group of patients with prolonged BT who had no alterations in platelet function tests that could explain their deranged primary hemostasis (vascular abnormalities? unidentified platelet dysfunction?). As for cirrhotics, these effects of DDAVP might be exploited when surgical procedures must be carried out and a shortening of the BT must be obtained rapidly, but clinical experience is needed to validate this hypothesis. There is little justification for giving DDAVP to patients with thrombasthenia, in agreement with Kobrinsky et al,[4] or to those with severe thrombocytopenia because the BT was not shortened. Unlike Kobrinsky, we did not find a significant shortening of the BT in patients with congenital storage pool deficiency. However, the analysis of the responses of individual patients indicates that the BT became shorter than ten minutes in two and shortened from 29 to 11 minutes in one, even though it remained prolonged in the remaining four (Fig 3). Hence it appears that in storage pool deficiency there are both responders and nonresponders, and that the response cannot be predicted on the basis of criteria such as the degree of baseline BT prolongation (Fig 3) and platelet levels of serotonin and adenosine diphosphate (data not shown).

Even though this controlled study establishes more clearly the therapeutic indications and limitations of DDAVP in disorders of primary hemostasis, the mechanism of the action of the drug is still unknown. Its poor efficacy in severe thrombocytopenia indicates that some critical platelet number is necessary for the drug to be effective. Poor efficacy in thrombasthenia and, to a lesser extent, congenital storage pool deficiency would apparently indicate that the platelets must also function normally. On the other hand, DDAVP was efficacious in some but not all patients with congenital storage pool deficiency, in volunteers taking antiplatelet drugs such as aspirin and ticlopidine, both of which, and particularly the latter,[9,13] induce severe platelet dysfunction. Even though drug-induced inhibition of vascular prostacyclin generation shortens the BT in rabbits,[14] it is unlikely that, as suggested by others,[15] this is a major mechanism for the DDAVP shortening effect because DDAVP shortened the BT in volunteers treated with 500 mg aspirin, a dose high enough to abolish vascular prostacyclin production.[16,17] On the other hand, Belch et al[18] have previously shown that DDAVP stimulates the production of plasma prostacyclin, suggesting that prostacyclin might cause the facial flushing seen after intravenous administration of DDAVP. We[19] and others,[20] however, did not demonstrate any change of prostacyclin after DDAVP. In agreement with Brommer et al,[21] we have also found that aspirin intake did not abolish the flushing of the face seen after DDAVP. Hence prostacyclin has probably little to do with the effects and side effects of DDAVP. A recent study has shown that ticlopidine administration induces a thrombasthenic-like functional state in normal platelets.[12] It remains to be explained why DDAVP, which promptly shortened the prolonged BT in our volunteers taking ticlopidine, did not shorten the prolonged BT in congenital thrombasthenia.

We have previously postulated that large vWF multimers transiently released by DDAVP from cellular compartments might enhance platelet adhesion and potentiate primary hemostasis.[1] Even though this hypothesis has been subsequently corroborated by the finding of heightened platelet adhesion in normal volunteers after DDAVP,[22] additional factors must be advocated to explain the hemostatic effectiveness of DDAVP because although large vWF multimers were released in all the patients we studied, the BT was not shortened in all. Other biological changes induced by DDAVP were a shortening of the APTT, previously observed by others[4,23] and probably due to the high FVIII levels achieved; prothrombin time prolongation, probably due to plasma dilution after water retention induced by the antidiuretic effect of the drug[24]; whereas, unlike Kobrinsky,[4] we saw no significant fall of the platelet count. These changes, however, seem unlikely to provide clues for the effectiveness of DDAVP because they were not correlated with BT changes and occurred in all groups, regardless of the effectiveness of DDAVP on the BT.

NOTE ADDED IN PROOF

At the time this manuscript was accepted for publication, Burroughs et al (Br Med J 291:1377, 1985) showed that DDAVP significantly shortened bleeding time in cirrhotics.

Responses of Hemopoietic Precursors to 13-cis Retinoic Acid and 1,25 Dihydroxyvitamin D_3 in the Myelodysplastic Syndromes

By Grant Swanson, Vincent Picozzi, Rodman Morgan, Frederick Hecht, and Peter Greenberg

To determine the effects of the "maturation-inducing" agents 13-cis retinoic acid and 1,25 dihydroxyvitamin D_3 on marrow cells from normal individuals and patients with myelodysplastic syndromes (MDS), we assessed marrow hemopoietic clonogenicity and differentiation response patterns to these agents. These vitamins caused increased proliferation in vitro of normal clonogenic marrow myeloid precursor cells (CFU-GM), decreased erythroid precursors (BFU-E), and no change in multipotent stem cells (CFU-GEMM). Marrow hemopoietic colony-forming cell incidence was generally subnormal in the 22 MDS patients evaluated. In vitro exposure to both agents caused various patterns of alteration of MDS hemopoietic colony and cluster formation, with similar but more pronounced effects evoked by retinoic acid. In the vast majority of MDS patients, enhanced marrow clonal granulocyte-monocyte differentiation and decreased BFU-E growth were noted after in vitro exposure to these vitamins. Correlation of biological effects was demonstrated between in vivo changes of peripheral neutrophil counts and in vitro responses of myeloid precursors for ten MDS patients treated with an eight-week therapeutic course of retinoic acid. Cytogenetic analyses indicated persisting aneuploidy or coexisting normal and aneuploid karyotypes in the cultured MDS myeloid cells and (with one exception) in native marrow cells from the treated patients. The varying responses of the MDS cells may monitor differing proportions of normal versus leukemic marrow cells susceptible to proliferative and differentiative expression on exposure to these agents.

THE MYELODYSPLASTIC SYNDROMES (MDS) provide a clinical setting for the evaluation of a group of relatively indolent disorders with a propensity to evolve into acute myeloid leukemia (AML). Controversy exists regarding prospective categorization of these patients as preleukemic. In vitro marrow culture studies and marrow cytogenetics are biological parameters that have been useful in characterizing this group of patients with regard to their potential for blastic transformation and for survival.[1,2] These studies have also improved our understanding of possible pathogenetic mechanisms underlying these disorders. Current management of these patients during their chronic indolent phase has generally been limited to supportive measures. However, recent approaches to therapy have included the use of such "maturation-inducing" agents as retinoic acid, vitamin D, and low-dose cytosine arabinoside.[3–5] These treatment regimens are based on the concept that a critical lesion underlying leukemia relates to an uncoupling of proliferation and differentiation at the level of the hemopoietic stem cell.[6–10] Induction of differentiation in culture diminishes the ability of leukemic stem cells to self-generate in vitro and reduces in vivo leukemogenicity.[7,8,10,11] Studies with murine models have demonstrated increased survival of animals with induced leukemia after their in vivo treatment with humoral inducers of myeloid differentiation or vitamin D.[11,12]

Due to the reported effects of retinoic acid and vitamin D on the proliferative and differentiative potential of normal and leukemic cells in vitro,[13–18] we have further assessed the in vitro hemopoietic clonogenicity and differentiation patterns of normal and MDS marrow cells in response to these maturation-inducing agents. To determine whether biological alterations occur after in vivo treatment of MDS patients with retinoic acid, we also evaluated marrow cytogenetics and in vitro clonal responses to these agents before and after an eight-week clinical trial of oral 13-cis retinoic acid therapy.

MATERIALS AND METHODS

Colony formation by granulocyte–macrophage (CFU-GM), erythroid (BFU-E), and pluripotent (CFU-GEMM) progenitor cells. Marrow cells were obtained by aspiration after informed consent was given in accordance with guidelines established by the Stanford Human Experimentation Committee. The cells were washed and then suspended in Iscove's medium containing 15% fetal calf serum (FCS) (Hyclone, Logan, Utah). The buoyant (<1.077 g/cm^3) mononuclear marrow cells were procured after centrifugation through Hypaque-Ficoll. To determine CFU-GM, 1.5×10^5 marrow cells were plated in 35-mm Lux dishes in 1 mL of a mixture of Iscove's medium, 1.1% methylcellulose, 30% FCS, and 15% human placental conditioned medium (HPCM) as a source of colony-stimulating factor (CSF-GM), as previously described.[19,20] Myeloid colonies and clusters were generally counted after ten days of incubation at 37 °C in a humidified incubator containing air—5% CO$_2$ To determine BFU-E and CFU-GEMM, cells were cultured as described but with 30% FCS in the Iscove's medium–methylcellulose mixture plus 5×10^{-5} mol/L 2-mercaptoethanol, 0.9% deionized bovine serum albumin (BSA), 1 μ/mL human urinary erythropoietin, and 1% of a T cell line conditioned medium (MoCM).[20,21] Leptalb-7 (Bovuminar—30% solution, Armour Pharmaceutical Co, Tarrytown, NY) with added sodium bicarbonate (0.08%) provided the BSA used for aiding support of BFU-E and CFU-GEMM growth. Erythroid bursts (BFU-E) and CFU-GEMM were counted on day 14 of culture. The colonies were counted using an inverted

microscope at 30× Representative colonies (10% to 20% of CFU-GM, myeloid clusters [possessing less than 50 cells per aggregate], BFU-E, and most CFU-GEMM) were picked, and cytocentrifuge preparations were made for Wright's-Giemsa and (for CFU-GM) chloroacetate and alpha naphthyl acetate esterase staining to assess their morphology.[22] All CFU-GEMM had a mixture of myeloid and erythroid cells, and some of these colonies also possessed megakaryocytes. To evaluate differentiation patterns of CFU-GM, three types of myeloid colonies were enumerated: "large cell," compact "small cell," and dispersed "small cell," which were found by Wright's-Giemsa and esterase staining to be monocyte-macrophages, blasts/immature granulocytes, and mixed immature/mature granulocyte-monocyte colonies, respectively. When assessed after ten days of incubation, the distribution of HPCM-stimulated normal marrow myeloid colony types was 5% ± 1%, 18% ± 2%, and 77% ± 3% (mean ± SE), respectively

Drugs, stimuli. 13-cis retinoic acid (retinoic acid), all-trans retinoic acid, retinol, and 1,25 dihydroxyvitamin D_3 (vitamin D) (kindly provided by Dr Milan Uskokovic, Hoffmann-LaRoche Inc, Nutley, NJ) were diluted in absolute ethanol (final concentrations ≤0.01%) and stored at −20 °C in containers gassed with nitrogen. Because these agents are light sensitive, the tubes and dishes containing them were shielded from light. CSF-GM for the in vitro studies was provided from HPCM.[20,23] Partially purified human urinary erythropoietin (1,140 U/mg protein) was obtained from the National Institutes of Health. The MoCM was kindly provided by Dr David Golde, UCLA Medical Center.[24]

Cytogenetics. Chromosome analyses were determined for native marrow cells and from cells incubated in vitro in clonogenic methylcellulose culture. Karyotypes from the prophase and prometaphase preparations of marrow cells thus obtained were analyzed by Giemsa banding after methotrexate/thymidine synchronization by Dr Fred Hecht and colleagues at the Southwest Biomedical Research Institute, Tempe, Ariz, as previously described.[25,26] A minimum of 15 chromosome spreads were analyzed per study. To obtain karyotypes of the cells cultured in vitro, the 1-mL methylcellulose-media gels containing the cells in the tissue culture plates were solubilized after ten days in culture by adding 6 mL of Iscove's medium plus 15% FCS (three 2-mL washes). The cell pellet obtained by centrifugation (400 g, five minutes) was resuspended, and 25 ng of Colcemid (GIBCO, Grand Island, NY) per 2 mL was added for two hours along with 15% HPCM, mixing gently every 30 minutes. The cells, obtained again by centrifugation, were resuspended in 2 mL of prewarmed 0.075 mol/L KCl for ten minutes at 37 °C. Cell fixation with 4 mL 3.1 methanol/glacial acetic acid was performed by slow mixing for ten minutes. The fixed cells were centrifuged, the cell pellet recovered, and 2 mL fixative was added. The cells were dispersed, incubated for ten minutes at room temperature, centrifuged, and resuspended in 1 mL of the fixative. From a height of about 15 cm, approximately 250 µL of cell suspension was added dropwise onto slides that had been presoaked in 70% ethanol and then flame dried.

Patients. Marrow specimens from 15 normal individuals (median age 59) and from 22 patients with MDS were studied. The 21 adult patients were elderly, median age 71 years old The MDS patients evaluated were separated into two groups. All patients were studied at initial clinical evaluation. Group I (ten patients) were subjects who received 13-cis retinoic acid therapy orally for eight weeks after in vitro marrow culture studies, five of whom were restudied within one to two weeks after discontinuing treatment. No patient had marrow culture studies performed during retinoic acid therapy. Group II (12 patients) were subjects who had the in vitro marrow culture studies performed but did not receive retinoic acid treatment (Table 1). Diagnostic criteria for the MDS (also termed smoldering myeloid leukemic states[1]), have previously been described and include refractory cytopenias for at least two months in patients with specifically abnormal marrow morphology. These syndromes have previously been categorized as hemopoietic dysplasia (preleukemia), smoldering or subacute myeloid leukemia (SML), and refractory anemia with excess of myeloblasts (RAEM).[1,2,27-32] Hemopoietic dysplasia has been defined as showing dysplastic maturation of marrow elements in at least two of the three major cell lines, including such qualitative changes as megaloblastoid erythropoiesis, ringed sideroblasts, defective myeloid differentiation, nucleocytoplasmic asynchrony, and dwarfed or abnormal megakaryocytes. SML has been defined by these characteristics and with 10% to 30% marrow myeloblasts, some degree of myeloid maturation, and an indolent clinical course. This categorization, rather than the French-American-British (FAB) reclassification proposal, has been used to describe MDS patients for reasons of historical usage and because of ambiguity of certain FAB formulations.[1] Eighteen of our patients had hemopoietic dysplasia and four had SML Initial clinical features of these individuals are given in Table 1. All of the patients were anemic, three were thrombocytopenic, four were neutropenic, and 11 pancytopenic. Ten study patients were treated with 13-cis retinoic acid (Accutane, kindly provided by Dr Loretta Itri, Hoffman-LaRoche) after informed consent was given, following guidelines established by the Stanford University Human Experimentation Committee. Treated patients received 13-cis retinoic acid orally, 2.5 to 4 mg/kg/d for eight weeks, and then were reevaluated with blood counts and marrow aspiration, and assessment of marrow morphology within one to two weeks after discontinuing the drug. In six of ten treated patients, marrow cytogenetics were also reevaluated at this time. Blood counts were obtained weekly throughout the course of treatment. Repeat in vitro marrow cell culture studies were also performed in five of these patients at this time. The clinical features of these patients and in vivo results of the therapeutic trial are being reported more extensively in a separate communication.[33] Serum retinoic acid levels achieved in individuals receiving 2.5 mg/kg 13-cis retinoic acid ranged between 0.29 and 0.91 µg/mL (1 to 3 × 10^{-6} mol/L) four hours after their ingesting the drug (kindly performed by Harris Laboratories, Lincoln, Neb). Statistical analyses were performed using Student's *t* test and chi-square test with Yates correction.

RESULTS

Clonogenic proliferative responses of normal marrow hemopoietic precursors to retinoids and vitamin D. After in vitro exposure of normal buoyant marrow mononuclear cells to 10^{-5} to 10^{-9} mol/L retinoic acid and 10^{-7} to 10^{-10} mol/L vitamin D, for the entire cell culture incubation period, maximal stimulation of CFU-GM was noted at 10^{-6} mol/L for retinoic acid (223% ± 15% increment over CSF-dependent basal values, $P < .01$) and at 10^{-9} mol/L vitamin D (153% ± 8% increment, $P < .05$) (Fig 1). In contrast, for erythropoietin-dependent BFU-E, a 30% to 50% decrement ($P < .05$) was caused by both agents (Fig 1). A similar decrement occurred when dimethyl sulfoxide (DMSO) rather than ethanol was used as diluent (data not shown). No change in colony formation occurred for CFU-GEMM.

To assess the specificity of the 13-cis retinoic acid effects, similar in vitro studies were performed with the related vitamin A analogues all-trans retinoic acid and retinol. Our studies with normal marrow cells showed no alteration of CFU-GM and BFU-E growth after retinol exposure in vitro at concentrations of 10^{-5} to 10^{-9} mol/L, n = 2 (Fig 2). In contrast, when using all-trans retinoic acid, moderate increments in CFU-GM growth (130% ± 12% of basal values,

$P < .05$) occurred, with a peak at 10^{-6} to 10^{-7} mol/L, and decrements (70% ± 7% of basal values at 10^{-6} mol/L, $P < .05$) in BFU-E growth occurred, n = 3 (Fig 2).

Clonogenic proliferative and differentiative responses of MDS marrow hemopoietic precursors to retinoids and vitamin D. Twenty-two patients with MDS were evaluated with in vitro marrow culture studies. In these 22 studies, buoyant marrow mononuclear cells from 18 patients showed formation of CFU-GM, nine formed BFU-E, and two formed CFU-GEMM (Table 1, Fig 3). Colony formation, when it occurred, generally had a lower plating efficiency than that of controls, and four patients formed no colonies. No augmentation of colony formation occurred after in vitro exposure to retinoic acid (unchanged colony formation, Fig 3) or vitamin D in those patients initially lacking myeloid, erythroid, or mixed colony formation ("non-colony form-

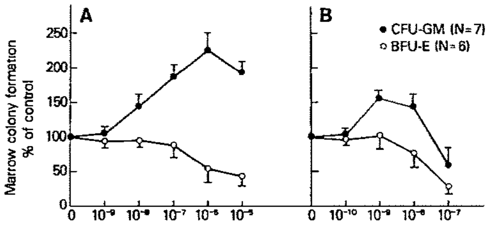

Fig 1. Proliferative responses of normal marrow myeloid (CFU-GM) and erythroid (BFU-E) precursors on in vitro exposure to (A) 13-cis retinoic acid; M, or (B) 1,25 dihydroxyvitamin D_3, M. Values represent means ± SE.

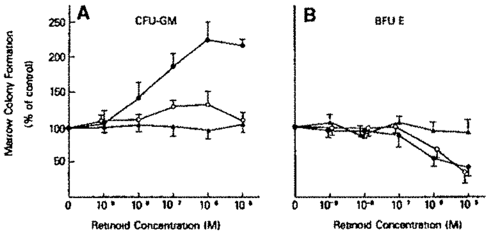

Fig 2. Proliferative responses of (A) normal marrow myeloid (CFU-GM) and (B) erythroid (BFU-E) precursors on in vitro exposure to various retinoid congeners: ●—●, 13-cis retinoic acid; ○—○, all-trans retinoic acid; and ▲—▲, retinol.

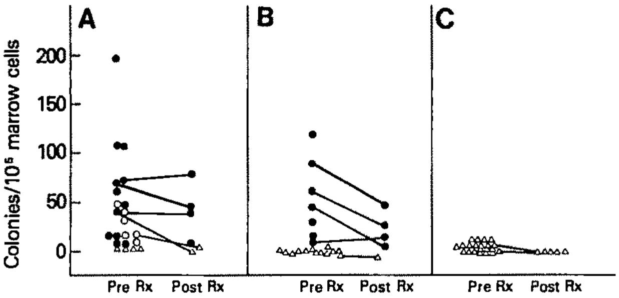

Fig 3. Marrow hemopoietic precursor [(A), CFU-GM; (B), BFU-E; (C), CFU-GEMM] colony formation in vitro from patients with myelodysplastic syndromes before and after in vivo treatment with 13-cis retinoic acid. Patterns of in vitro colony formation responses to in vitro exposure to 13-cis retinoic acid (10^{-6} mol/L) are also shown: ○, increased; ●, decreased; △, no change in colony formation.

ers") (Table 1). The same patients were simultaneously evaluated for growth of the three hemopoietic progenitor cells in the absence or presence of 10^{-6} mol/L retinoic acid (Fig 3). For the myeloid "colony formers," several patterns of in vitro response to the vitamins were noted, with more pronounced in vitro effects being seen after retinoic acid exposure than after vitamin D exposure (Fig 4). In the presence of retinoic acid, the number of CFU-GM was increased in six patients and decreased in 12 (13% to 100% change in colony formation, with the vast majority being >20% from baseline values; Fig 3). In 12 of these 18 patients, increased growth of clusters developed after in vitro exposure to retinoic acid. In vitro responses to retinoic acid of colonies and clusters together showed four growth patterns (a) increased CFU-GM and increased clusters (six patients); (b) decreased CFU-GM, no change in clusters (five patients); (c) decreased CFU-GM and increased clusters (six patients); (d) no change (five patients, four of whom initially formed no colonies). No association was found between initial colony-forming incidence and the pattern of response to retinoic acid. Further, no correlation was noted between initial clinical features, marrow morphology, cytogenetics, or in vitro responses to retinoic acid. When grown in the presence of vitamin D, an increase in CFU-GM incidence occurred in five patients, a decrease occurred in seven, and there was no change in one, compared with control values. Decreased BFU-E growth (22% to 96%; median, 33% of control) occurred in seven of the eight tested patients having erythroid growth ($P < .05$) after retinoic acid exposure but in only three of six patients after vitamin D exposure (NS). Except for two patients whose marrows had one to two mixed colonies per 10^5 cells plated, no CFU-GEMM were detected in marrow cells of the patients with or without vitamin exposure. Similar patterns of response of the marrow hemopoietic precursors from MDS patients occurred on in vitro exposure to retinoic acid and vitamin D (ie, concordance was found for 11 of 13 patients' myeloid growth patterns [CFU-GM, clusters], seven of eight patients' BFU-E, and all eight CFU-GEMM [Table 1, Fig 4]).

Effects on differentiation were assessed by noting whether an increase in the percentage of mature granulocyte or monocyte–macrophage type colonies occurred after exposure to these drugs. In the majority of patients, enhanced granulocyte–monocyte differentiation was noted after in vitro exposure to retinoic acid (in nine of 16 patients; 56%) or vitamin D (11 of 15 patients; 73%). Maximal changes in in vitro colony formation in MDS patients occurred at concentrations of retinoic acid (10^{-6} mol/L) and vitamin D (10^{-8} mol/L) that were similar to values obtained with marrow cells from normal individuals. No differences in differentiation potential were noted in cells with types (a), (b), or (c) growth patterns.

Biological effects of the in vivo therapeutic trial with 13-cis retinoic acid. Ten patients with MDS (group I) were treated with an eight-week course of oral retinoic acid, five of whom were restudied within one to two weeks after completion of therapy. No patients were studied during the time they were taking retinoic acid. Alterations of peripheral blood counts, marrow morphology, in vitro hemopoietic growth characteristics, and (see below) cytogenetic analyses were evaluated in these patients. After in vivo exposure to retinoic acid, these patients generally demonstrated no substantial changes from their initial colony-forming incidence or *patterns* of response to the drugs (Figs 3 and 5).

Correlations between in vivo hemopoietic responses to retinoic acid treatment and initial clonogenic growth patterns and in vitro responses to retinoic acid were evaluated (Table 1). Ten of the MDS patients (group I) studied with in

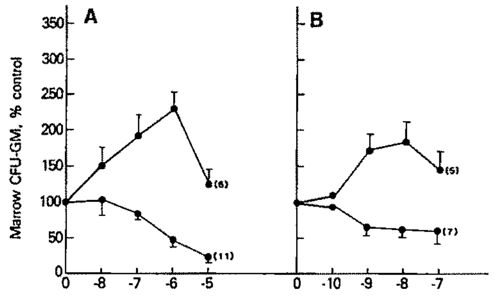

Fig 4. Proliferative responses of marrow myeloid precursors (CFU-GM) from myelodysplastic patients initially forming colonies who demonstrated increased (upper curve) or decreased (lower curve) colony formation upon in vitro exposure to (A) 13-cis retinoic acid, $\log_{10}$ M or (B) 1,25 dihydroxyvitamin D_3, $\log_{10}$ M.

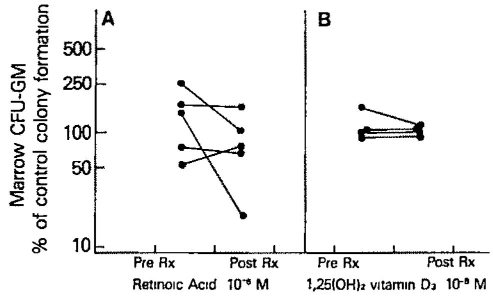

Fig 5. Proliferative responses of marrow myeloid precursors (CFU-GM incidence) from myelodysplastic patients upon in vitro exposure to (A) 13-cis retinoic acid 10^{-6} M and (B) 1,25 dihydroxyvitamin D_3 10^{-8} M and pre and post in vivo treatment with 13-cis retinoic acid.

vitro marrow clonogenic assays were treated with retinoic acid. Seven of the ten patients developed increments in peripheral blood neutrophil levels during therapy (114% to 700%; median, 145%) and three had decrements (31% to 71% of basal values; median, 67%). The improved neutrophil counts occurred by six to eight weeks of therapy and returned to basal levels within two to four weeks after cessation of therapy. There were essentially no changes in the patients' platelet counts, hemoglobin levels, or transfusion requirements during or immediately after the treatment course. No correlation was noted between in vivo responses to retinoic acid and the initial values for marrow CFU-GM, BFU-E, or CFU-GEMM incidence. All of these patients formed CFU-GM, and six had increased myeloid clusters (four patients whose neutrophils increased, two patients whose neutrophils decreased after therapy) in the absence of in vitro retinoic acid. After exposure of the marrow cells to 13-cis retinoic acid in vitro (10^{-6} mol/L), the myeloid growth patterns (a), (b), and (c) described earlier were noted. All seven patients with growth patterns (a) and (b), in response to in vitro retinoic acid exposure, subsequently developed increments in neutrophil counts after in vivo treatment, whereas the three patients with myeloid growth pattern (c) had decrements in their neutrophil counts (Table 1). These associations between in vivo responses and in vitro response patterns were statistically significantly different ($P < .05$). As BFU-E growth in treated patients either decreased (three patients) or (as with CFU-GEMM growth) was initially absent and did not alter (seven patients) after in vitro exposure to retinoic acid, correlations of BFU-E or CFU-GEMM responses with in vivo responses were not apparent. No correlations between marrow cytogenetic findings, clinical features (eg, presence or absence of neutropenia, other cytopenias, category of MDS), or in vivo responses to retinoic acid were noted in the group I patients.

Marrow cytogenetic analyses. Cytogenetic characteristics and marrow morphology of native marrow cells from normal and preleukemic patients before and after in vivo exposure to retinoic acid were determined. Twenty-one of the 22 patients had marrow cytogenetics assessed. Fourteen of the 21 patients (67%) had detectable chromosome abnormalities: four elderly males had cells that lacked the y chromosome in addition to normal cells, and ten had other abnormal karyotypes. Eight patients had chromosomal mosaicism with normal and abnormal cell lines, six had only abnormal chromosomes, and six had complex cytogenetic changes. In the group of ten patients receiving retinoic acid treatment (group I), one patient had a normal marrow karyotype, three were mosaics with loss of y chromosome, and the remainder had aneuploidy (Table 1). Shared chromosome abnormalities included partial deletion of chromosome 5 (patients 10 and 21), an isochromosome 17 (patients 6 and 9), and loss of the y chromosome in cells from four males (patients 2 through 4, 17). Six patients (1 through 5, 9) had posttreatment cytogenetics assessed, and with one exception (patient 5), no change was noted in these marrow morphological or chromosomal features after therapy. Patient 5, whose marrow chromosome pattern normalized after treatment, had morphological improvement in marrow granulocyte maturation and developed the most dramatic increase in blood neutrophil counts. In this patient, all of these parameters reverted to baseline values within one month after discontinuing treatment. No correlation was evident between marrow cytogenetics and the patients' clinical features, response to therapy, or in vitro hemopoietic growth patterns (Table 1).

Cytogenetic characteristics of both native marrow cells and marrow cells cultured in vitro from normal and MDS patients were determined. Cells stimulated by HPCM in methylcellulose clonogenic cultures were examined in the presence or absence of 10^{-6} mol/L retinoic acid exposure. Bone marrow cells cultured in vitro from two normal individuals (possessing normal marrow cell karyotypes) were analyzed and yielded normal karyotypes with or without in vitro retinoic acid exposure. Marrow cells from three MDS patients were examined in this fashion. One patient (12) had normal native marrow cell chromosomes and type (a) in vitro myeloid growth pattern responses to retinoic acid. This patient had normal metaphases demonstrated in cells obtained from methylcellulose gel cultures in the presence or absence of retinoic acid. Two MDS patients with either aneuploidy (patient 1) or a mixture of normal and aneuploid karyotypes (patient 15) were also evaluated. Patient 1's cells yielded chromosomes with the same abnormal karyotype as the native marrow in both the presence (wherein a 20-fold increase of clusters was generated) and the absence of in vitro exposure to retinoic acid. Both the normal and the abnormal karyotypes initially present in marrow cells from patient 15 were found after retinoic acid exposure in vitro, but only normal karyotypes were demonstrable in the absence of retinoic acid. Patient 1 also had persistence of his initial native marrow cytogenetics after in vivo treatment with retinoic acid.

DISCUSSION

These data describe clonogenic hemopoietic precursor proliferative and differentiative responses upon in vitro exposure of marrow cells from normal individuals and 22 patients with MDS to 13-cis retinoic acid and 1, 25 dihydroxyvitamin D_3. Confirming previous reports,[13,18] we showed augmentation of normal CFU-GM colony formation after in vitro exposure to 13-cis retinoic acid, all-trans retinoic acid, and vitamin D. The increases in normal marrow CFU-GM from vitamin D exposure were similar to those from retinoic acid but were less striking. These effects occurred at drug concentrations achievable by pharmacologic doses of retinoic acid administered in vivo (10^{-6} mol/L) but required doses higher than those attained (2×10^{-10} mol/L)[4] by treatment with 1,25 dihydroxyvitamin D_3. Substantial decrements in erythroid colony formation occurred after exposure to both drugs (again, requiring excessively high concentrations of vitamin D). The inhibitory effects on BFU-E growth were not attributable to the ethanol diluent, as control values with in vitro exposure to ethanol alone showed no such decrement, whereas use of another diluent (DMSO) in the presence of the vitamins demonstrated the inhibition. Prior studies have also shown no decrement in erythroid colony formation at the ethanol concentrations that we used ($\leq 0.01\%$).[34] As specificity controls, we demonstrated that retinol, a vitamin A analogue that is relatively inactive for hemopoietic growth-promoting functions,[13,15,16,35] caused no change in myeloid or erythroid colony formation in our subjects, whereas the active compound all-trans retinoic acid had effects similar to 13-cis retinoic acid (Fig 2). Significant decrements (median 33% of control) in BFU-E also occurred after in vitro retinoic acid exposure in the MDS patients who had erythroid growth (Table 1). This effect was not evident with vitamin D. The observed inhibitory effect of retinoic acid on BFU-E growth is at variance with one previously published study that found an increase in erythroid colony formation in the presence of retinoic acid.[15] We believe that the difference is at least partially attributable to the fact that the previous study examined circulating peripheral blood BFU-E, whereas we evaluated bone marrow erythroid precursors. Marrow and peripheral blood BFU-E have differing sensitivities to erythropoietin levels.[36] Concentration-dependent effects of marrow adherent cells on in vitro erythropoiesis have been demonstrated, with inhibitory effects on erythroid precursors occurring in the presence of high concentrations of these adherent monocytic cells or their culture supernatants.[37,38] Modulation of several functions of adherent cells (eg, macrophages) and subsets of T lymphocytes occurs after their exposure to retinoic acid.[39,40] Thus, functionally disparate accessory cell populations activated by retinoic acid or the BFU-E themselves, which are present within peripheral blood *v* bone marrow, may play a role in the contrasting results of our study and that previously reported. Further investigation of this issue is needed.

Low values for marrow CFU-GM and BFU-E frequency were found in the majority of marrow specimens from the MDS patients, as previously described.[41–47] The marrow cells from 18 of 22 MDS patients formed CFU-GM, nine formed BFU-E, but only two formed CFU-GEMM. The data, demonstrating marked diminution in CFU-GEMM colony formation in the MDS patients, indicate that these three precursors share the quantitative hemopoietic defects present in the disorder. The absence, rather than low numbers, of CFU-GEMM may reflect their relatively low incidence in marrow (and the limited quantity of cells plated). The addition of retinoic acid or vitamin D caused no augmentation of colony formation in those individuals initially lacking in vitro clonogenicity. The data indicate that the vitamins do not overcome the basic lesion(s) in in vitro proliferative potential of the nonclonogenic MDS hemopoietic precursors.

Increased differentiation of myeloid colonies to more mature granulocytes and monocytes was noted in the majority of MDS patients after in vitro exposure to retinoic acid (56%) or vitamin D (73% of patients). Other recent studies have also demonstrated enhanced monocyte–macrophage differentiation of colonies from normal and leukemic marrow after in vitro exposure to 1,25 dihydroxyvitamin D_3.[18,48] In the "colony formers," various patterns of response to retinoic acid and vitamin D in vitro were noted, with similar but more pronounced effects being seen with retinoic acid. Several patterns of myeloid growth after in vitro exposure to these agents were discerned: (a) increased CFU-GM and increased cluster formation, (b) decreased CFU-GM, (c) decreased CFU-GM and increased cluster formation, (d) no change. The varying responses of MDS cells may reflect our monitoring the growth of different proportions of normal *v* leukemic cells that were susceptible to proliferative or differentiative expression on exposure to these drugs. In addition, the presence of qualitative or quantitative differences in the accessory cells affected by these vitamins could have contributed to the diminished erythroid clonal growth patterns.

Biological effects of the relatively short (eight-week) trial of retinoic acid therapy on marrow cells were assessed in these MDS patients. After in vivo treatment of patients with retinoic acid, no clear alteration occurred in the in vitro colony-forming incidence or response to these agents for marrow CFU-GM, BFU-E, or CFU-GEMM. This finding was associated with the lack of alteration in marrow morphology or cytogenetics in virtually all of these patients. Correlations between in vivo responses to retinoic acid treatment and the responses of clonogenic myeloid cells to retinoic acid exposure in vitro were found: the seven MDS patients with patterns (a) and (b) after retinoic acid exposure in vitro subsequently developed increments in peripheral neutrophil counts after treatment, whereas neutrophil decrements developed in the three patients who had generated pattern (c) in vitro. No correlations were found between in vivo responses and values of initial marrow CFU-GM, BFU-E, or CFU-GEMM incidence in vitro or marrow cytogenetics. In a separate paper, we present more extensive data detailing the clinical features and in vivo responses of MDS patients to retinoic acid therapy.[33]

Nonrandom marrow cytogenetic abnormalities have been reported in a substantial proportion of patients with MDS[49–52] and were present initially in 14 of our 21 patients (67%) so evaluated. The recurring chromosomal abnormalities we found were partial deletion of the chromosome 5 long (q) arm, isochromosome 17, and loss of the y. These abnormalities are associated with MDS, and isochromosome 17 may be found in the blastic phase of chronic myelocytic leukemia.[1,25,49–52] Loss of the y chromosome is a common feature in elderly males and appears to be a reflection of aging.[53] These cytogenetic findings support the concept of the MDS as representing a clinically relatively indolent spectrum of clonal hemopathies. The clonal nature of these disorders and the qualitative cellular and biological abnormalities similar to those occurring in AML strongly suggest that the patients initially demonstrate critical neoplastic features. This group of disorders appears to represent coexisting normal and leukemic clones within marrow in which the host copes effectively with the leukemic clone or is populated by a leukemic clone with potential for greater in vivo differentiation.

To more clearly determine whether normal or abnormal clonal growth was altered by retinoic acid exposure, cytogenetic analyses were performed before and after retinoic acid therapy in six patients. Five of these individuals showed no alteration in their native marrow cell karyotypes. Three of these treated patients also had karyotypic analysis performed on cells present in their myeloid colonies grown in vitro in the presence and absence of retinoic acid. These in vitro and in vivo results demonstrated, with the one exception, the persistence or enhanced generation of the clones initially present in the patients' native marrow cells on retinoic acid exposure. The data are consistent with the hypothesis that retinoic acid increased the differentiation or proliferation of the endogenous marrow myeloid clones (normal and abnormal) in the MDS patients. The implications of enhanced abnormal (possibly leukemic/preleukemic) clonal proliferation in vitro in several of our patients need to be addressed. Clonal proliferation in the bioassay system that we used is accompanied by cell differentiation. Induced differentiation of leukemic cells has been shown to be associated with their decreased capacity for self-replication and leukemogenicity.$^{7-11,54}$ None of our treated patients had an increase in peripheral blood or marrow blast cells or underwent evolution to overt leukemia during the therapeutic trial. These findings provide no evidence for adverse hematologic effects of the retinoic acid exposure. However, further followup is needed to determine the long-term effects of this therapy on the patients' clinical outcomes. The temporary normalization of marrow cytogenetics in the one patient having the most striking improvement in neutrophils after in vivo retinoic acid therapy suggests treatment-induced improved growth potential of a karyotypically normal residual hemopoietic clone in this patient's marrow. The absence of correlation between marrow cytogenetic abnormalities and the in vitro or in vivo myeloid responses to retinoic acid suggest that factors distinct from detectable chromosome constitution regulate such an interplay (eg, retinoid binding proteins, effects of retinoids on accessory cells or on growth factors modulating hemopoietic precursors, alterations of cellular onc genes regulating cellular differentiation and proliferation).^{35} Such interactions between retinoids and growth factors have been demonstrated in other cell systems.^{35,55} Retinoic acid-induced differentiation is associated with altered expression of cellular oncogenes ^{56} Further evaluation is necessary and appears warranted to determine whether the natural history of MDS will be altered by more prolonged treatment of these patients with retinoic acid.

ACKNOWLEDGMENT

We are indebted to Drs A. Barkin, T. Cohen, D.P. Cooney, J. Krakower, K. Porzig, M. Rubinstein, B. Sikic, and R. Stebbins for referring several of the patients evaluated in this study.

Cytomegalovirus Infection After Bone Marrow Transplantation: An Association With Acute Graft-v-Host Disease

By Wesley Miller, Patrick Flynn, Jeffrey McCullough, Henry H. Balfour, Jr, Anne Goldman,
Robert Haake, Philip McGlave, Norma Ramsay, and John Kersey

Among 181 patients undergoing allogeneic bone marrow transplantation over a five-year period (1978 through 1982), cytomegalovirus (CMV) infection was a frequent and often lethal complication. Recipient pretransplant serology was the most important predictor of posttransplant CMV infection. CMV infection occured in 26/137 seronegative recipients and in 28/44 seropositive recipients ($P < .001$). Among patients who developed CMV infection, the time to infection was identical in seronegative and seropositive patients (median, 71 days post transplant). Bone marrow donor CMV serology did not significantly influence CMV infection rate. CMV infection was strongly associated with acute graft-*v*-host disease (AGVHD), occurring in 34/81 patients with AGVHD and 20/100 without GVHD ($P < .001$). AGVHD preceded CMV infection by 33.7 days (mean) in patients developing both complications. Patients who developed CMV infections had also received more cellular blood products post transplant. These data suggest that CMV infection may occur through reactivation of latent virus (in seropositive recipients) or through exogenous exposure, possibly through transfused blood products, but that duration of immunoincompetence may be more critical than route of exposure in timing of clinically evident CMV infection. Prophylaxis tailored to the likely infectious source and more effective GVHD prevention both may be critical in preventing CMV infection after bone marrow transplantation.

© 1986 by Grune & Stratton, Inc.

BONE MARROW TRANSPLANTATION is increasingly successful in the treatment of a variety of hematologic and immunologic disorders. Although transplantation is effective in restoring hematopoiesis, the early complications of graft-*v*-host disease (GVHD) and infection (especially viral) limit the success of this treatment modality. Cytomegalovirus (CMV) infection has been documented in 40% to 50% of patients undergoing marrow transplantation, with adults developing CMV infection more frequently than pediatric patients.[1,2] In addition, interstitial pneumonitis, a severe and often fatal complication, is commonly associated with CMV infections.[1]

In bone marrow transplantation, immunosuppression is multifactorial. Immunoincompetence may result from the patient's primary disease, from the preparative regimen, from GVHD, or from treatment of GVHD. Several sources of CMV infection must also be considered. Immunosuppression may allow reactivation of latent virus in CMV seropositive patients. CMV might be transmitted with transplanted marrow from a seropositive donor. Finally, the multiple blood products that most patients receive in the early post-transplantation period may contain infective CMV particles. In an attempt to clarify the relative importance of these causes of immunosuppression and sources of infection, we analyzed the University of Minnesota experience with CMV in bone marrow transplantation over a five-year period.

METHODS AND MATERIALS

Patients. During a five-year period (1978 through 1982), 206 patients underwent allogeneic bone marrow transplantation at the University of Minnesota Hospitals Of these patients, 13 were eliminated from analysis because they were excreting CMV before transplantation and 12 patients were eliminated because of inadequate data regarding donor CMV serology. Thus 181 patients were retrospectively analyzed for their entire posttransplant course. Both adult and pediatric patients were included. Patients were grouped according to CMV serology before transplantation and by age (younger than 16 years old or 16 years or older). Forty-one recipients and 50 donors were judged seropositive on the basis of positive complement fixation titers, while three recipients and three donors were judged seropositive on the basis of positive immunofluorescence titers (with negative complement fixation). Blood, urine, and throat cultures for CMV were obtained and serum titers determined for each patient weekly during hospitalization and again at posttransplant day 100. Complement fixation titers were done on all samples, although not all negative complement fixation titers were retested by immunofluorescence. At day 100, both complement fixation and immunofluorescence titers were determined for all patients. Additional cultures were obtained as clinically indicated. Prospectively collected data regarding patient age, disease, conditioning regimen, GVHD, CMV infection, and survival were available from the University of Minnesota Bone Marrow Transplant Database Management under the direction of Dr Anne Goldman.

Definitions. Seropositivity for CMV was defined by a complement fixation titer of ≥1:8 or an immunofluorescence titer of ≥1:40. Seropositivity was interpreted as indicating prior exposure, not active infection. All CMV infections were diagnosed on the basis of positive CMV culture from any site, tissue biopsy showing typical CMV inclusions, or a fourfold increase in titers of antibody against CMV. Our methods for culturing CMV and performing humoral titers were as previously described.[3]

GVHD was diagnosed on the basis of clinical findings (rash, diarrhea, abdominal pain, hepatomegaly, jaundice, elevated liver enzymes), coupled with histologic changes of GVHD in biopsies of skin, liver, or gastrointestinal tract (stomach, duodenum, colon), using standard criteria.[4] Any patient with at least grade 1 GVDH was considered to have GVHD.

Blood product usage. We evaluated the number of cellular blood products administered to each patient included in the study. For each patient, red blood cell units, platelet donor units, and granulocyte donor units were enumerated. Pediatric patients

received smaller packed red cell units (125 mL) than did adult patients (approximately 300 mL), but platelet units were the same size for pediatric and adult patients. Cellular blood products were enumerated for each patient during the first 35 days after transplantation. Because the usual onset of detectable CMV infection is at post-bone marrow transplant day 50 to 55,[1,2] it is likely that virus transmission or reactivation occurs during the early posttransplant period. In addition, CMV infection may increase transfusion requirements, and analysis of blood product requirements for the entire posttransplant course might not accurately reflect differences in blood product usage before CMV infection. We, therefore, evaluated blood product transfusion for each patient before the usual onset of CMV infection. (Complete transfusion data were not available for five patients. All five patients were seronegative, and only one developed CMV infection: a 14-year-old female, who died at posttransplant day 238 of relapsed acute lymphocytic. leukemia (AML). Of the remaining four, a 27-year-old male died at day +174 of relapsed chronic myelogenous leukemia (CML). The others remain alive without disease.)

Statistics. CMV incidence curves were estimated by the Kaplan-Meier product limit method similar to survival analysis, except that all patients were considered at risk for CMV until censoring at the time of death. The cumulative event proportions at one year were compared by t tests. Some factors that significantly affected CMV infection rates were also associated with one another (eg, age and GVHD). To study these associations, Cox multivariate regression analysis was carried out, using proportional hazards methods[5] for CMV incidence and for survival. For this purpose, we used the P2L program from BDMP Statistical Software, Inc (Los Angeles). GVHD occurs some time after transplant and was therefore treated as a time-dependent covariate in the Cox model.[6] Differences in blood transfusion amounts (comparing number of units received by patients developing CMV infection with the number of units received by patients remaining CMV-free) were analyzed using the Mann-Whitney rank sum test.

Autospy data. Autopsy reports were available for 50 patients included in this study group. Autopsy reports were reviewed for evidence of CMV infection and for distribution of CMV at autopsy. CMV was identified histologically by the presence of typical intracellular inclusions in tissue specimens.

RESULTS

CMV infections were documented in 29.8% of bone marrow transplant patients. CMV infection was diagnosed by positive cultures in 46 patients, compatible tissue morphology in two, and seroconversion in six patients. (Five of these patients were seronegative before transplant; the sixth patient had CMV titers of 1:16 by complement fixation and 1:20 by immunofluorescence before bone marrow transplantation that rose to 1:64 by immunofluorescence and 1:640 by complement fixation during the posttransplant course.) We evaluated several factors that might predict risk for development of CMV. The first of these, recipient and donor serology prior to bone marrow transplantation, are shown in Table 1. Among 137 seronegative patients, 26 (estimated infection rate, 22.8%) developed CMV infection, while 28/44 (estimated infection rate, 79.6%) of seropositive patients developed CMV infection during the posttransplant course ($P < .001$). The titer of CMV antibody present pretransplant, on the other hand, did not appear to influence infection rate. Among seropositive recipients, those with CMV complement fixation titers of 1:8 to 1:16 developed CMV infection in 15/21 cases. Recipients with complement fixation titers of 1:32 to 1:512 developed CMV infection in 14/23 cases. Thus recipient seropositivity (but not titer) was strikingly important in predicting CMV infection. Severity of infection was not apparently influenced by pretransplant serology, however. Twenty-three patients (12 seronegative and 11 seropositive) developed clinically apparent disease, while 31 patients had subclinical infections. Bone marrow donor serology, in contrast to recipient serology, had no significant influence on posttransplant CMV infection (32.7% *v* 47.6%, $t = 1.6, p = .12$) (Table 1).

We also analyzed the time to CMV infection for patients who actually became infected. The median time to diagnosis in patients developing CMV infection was 71 days post-bone marrow transplantation. Interestingly, neither recipient nor donor pretransplant serology appeared to influence the time to infection. Seropositive recipients and seronegative recipients had identical time curves (Kaplan-Meier) for acquisition of CMV infection, both with medians of 71 days. This analysis may be biased, since the 51 patients who died without CMV were not included in these particular calculations.

Patients developing CMV infections were somewhat older (mean age, 17.5 years) than patients remaining free of CMV (mean age, 13.9 years). Time to CMV infection was examined using the Cox regression method with age as a covariate. Increasing age was a significant predictor of time to CMV; each additional year of age was associated with a 1.032 proportional increase in the likelihood of CMV infection. The increased risk in adults appears to relate to the increasing incidence of seropositivity with increasing age. Seropositive recipients had a mean age of 21.1 years, whereas seronegative recipients had a mean age of 13.0 years. When seronegative patients were grouped by age, patients of less than 16 years of age (mean, 7.4 years) had an 18.8% incidence of CMV infection (16/85), while seronegative

Table 1. CMV Infection After Bone Marrow Transplantation: Relationship to Recipient/Donor Pretransplant CMV Serology

	Recipient Serology			
	Negative	Positive	Total	Estimated Incidence*
Donor Serology				
Negative	20/107	15/21	35/128	32.7% ± 4.7% SE
Positive	6/30	13/23	19/53	47.6% ± 8.3% SE
Total	26/137	28/44	54/181	
Estimated incidence†	22 8% ± 4.0% SE	79 6% ± 7.4% SE		

* *t* Test on cumulative proportion without event by donor serology is 1.56, $P = 12$

† *t* Test on cumulative proportion without event by recipient serology is 6.73, $P = .001$.

patients of 16 years or older (mean age, 22.2 years) had a nearly identical 19.2% (10/52) incidence of CMV infection. With Cox regression, age did not independently predict CMV infection when recipient serology and GVHD were included as covariates (Table 2).

The conditioning regimens used in bone marrow transplantation are a source of variation among patients. We evaluated the relationship between conditioning regimens and CMV infection rate. Seronegative patients receiving total body irradiation (chiefly for malignancies) had an 18.4% (19/103) incidence of CMV infection, while those receiving total lymphoid irradiation (chiefly for aplastic anemia) had a 23.3% (7/30) incidence of CMV infection ($\chi_c^2 = 0.11$, $P = .74$). Similarly, seropositive patients receiving total body irradiation had a 59.3% (16/27) incidence of CMV infection compared with 70.6% (12/17) for those receiving total lymphoid irradiation ($\chi_c^2 = 0.19$, $P = .66$). Four patients received chemotherapy without irradiation before transplantation, and none of these developed CMV infection.

The relationship between blood tranfusions and CMV infections in our patients is shown in Table 3. Patients who remained CMV-free received 33.3 units of blood (median), while those who developed CMV infection received more, with a median of 46.5 units of blood during the first 35 days after transplantation ($P = .08$). We also analyzed red blood cell and platelet transfusions for each patient. CMV-infected patients received significantly more red cell units (6.1 units, median) than did uninfected patients (5.0 units, median) ($Z = 1.96$, $P = .05$). CMV-infected patients also received more platelets (37.0 units) than did uninfected patients (25.5 units), although this difference was not statistically significant ($Z = 1.28$, $P = .12$ by Mann-Whitney). The products administered were not tested for CMV antibody. However, the overall incidence of CMV seropositivity in our blood donor population is 30%.

The association between acute GVHD (AGVHD) and CMV infection is shown in Table 4. Among patients with no AGVHD, 20% had posttransplant CMV infections, while 42% of those with AGVHD developed CMV infections. A Cox proportional hazards regression analysis was performed in which AGVHD was included as a time-dependent covariate. In this analysis of time to CMV, patients were included in the no AGVHD group until the time of diagnosis of AGVHD; at that point patients were switched to the AGVHD. Thus if CMV was evident before the diagnosis of AGVHD, the risk of CMV would be associated with no AGVHD; when AGVHD preceded CMV, the risk of CMV infection was associated with AGVHD. CMV infection was significantly more likely to occur among patients with AGVHD. The relative risk for those with AGVHD was 3.24 times that for those without AGVHD ($P < .001$). A similar regression analysis of time to CMV was conducted with chronic GVHD as a time-dependent covariate, but this analysis failed to show an association of CMV with chronic GVHD (relative risk of CMV = 1.63, $P = .40$). Among patients surviving longer than 100 days, chronic GVHD was diagnosed in 22/93 (23.7%) CMV-uninfected and 15/39 (40.5%) CMV-infected patients ($\chi_c^2 = 2.3$, $P = .13$).

To further clarify the relationship between AGVHD and CMV, we compared the time to CMV and time to AGVHD in 24 patients who developed both. Acute GVHD preceded diagnosis of CMV by a mean of 33.7 days in these patients ($t = 4.17$, $P < .001$). Because AGVHD preceded CMV infection in most patients, we next sought a relationship between treatment of AGVHD and CMV infection. Table 5 shows CMV infection incidence according to maximal GVHD therapy. Patients were treated with topical or moderate- or high-dose corticosteroids, depending on the distribution and severity of AGVHD. As can be seen, although AGVHD appeared to influence CMV infection rate, the dose or route of administration of GVHD therapy did not obviously affect CMV infection rate. Among seronegatives, the CMV infection rate was similar whether the patient received topical or moderate- or high-dose steroids ($\chi_c^2 = .44$, $P = .80$). Similarly, seropositive patients with AGVHD had nearly identical CMV infection rates regardless of GVHD therapy ($\chi_c^2 = .11$, $P = .74$).

Because recipient CMV serology, GVHD, age, and CMV infection were all interrelated factors, their association was further analyzed using Cox regression analysis. This method allowed us to test the association between rate of CMV infection and each of the factors while controlling for the effects of each of the remaining factors (Table 2). Both recipient serology and AGVHD were confirmed as significantly and independently related to CMV infection (both $P < .001$). Age, when we controlled for the effects of serology and AGVHD, did not contribute significantly to CMV risk ($P = .41$).

We evaluated the effect of CMV infection on survival. Of

Table 2. Cox Regression Analysis of Variables Relating to CMV Infections

Variable	Relative Risk	*P* Value

Methylprednisolone (30 mg/kg/d)	5/16	8/9

patients developing CMV infection, 23/54 (43.0%) are alive one to five years after transplant, while 69/127 (54.3%) patients not developing CMV infection remain alive. Such data may not, however, accurately reflect the effect of CMV on survival. We therefore performed a multivariate analysis of the influence of various factors on survival. Factors included age (<16 *v* 16 or older), disease category (malignancy *v* other), high- *v* low-risk disease (see later), presence or absence of CMV infection, and presence or absence of GVHD. Patients were considered high risk if they were transplanted with acute nonlymphocytic leukemia (ANLL) in second or greater remission or in relapse; acute lymphocytic leukemia (ALL) in third or greater remission or in relapse; CML in accelerated phase, blast crisis, or post–blast crisis; neuroblastoma (three patients); or Burkitt's lymphoma transplanted in relapse (two patients). One patient with Fanconi's anemia was also included in the high-risk category. Patients were considered low risk if they were transplanted with ANLL in first remission; ALL in first or second remission; CML in chronic phase; or aplastic anemia. Using Cox regression analysis, we analyzed the independent effects of these factors on survival, using disease category, risk category, and age as baseline characteristics and including CMV and GVHD as time-dependent covariates, since they are not baseline characteristics. CMV infection was associated with decreased survival (relative risk 2.1, P = .005), as was high-risk disease (relative risk 1.72, P = .03). Age (relative risk 1.31), disease category (relative risk 1.13), and GVHD (relative risk 1.4) were not independent predictors of survival in this analysis. In a separate analysis of 101 leukemic patients, we compared the effects of diagnosis (ANLL *v* ALL *v* CML), age, risk, CMV infection, and GVHD. Diagnosis did not influence survival (relative risk 1.0), while CMV infection again showed a negative influence on survival (relative risk 2.4, P = .01), as did high-risk disease (relative risk 2.0, P = .025). This multivariate analysis clearly demonstrates that CMV infection was associated with an increased mortality and indicates that the overall risk of death among CMV-infected patients was 2.1 times that of those without CMV.

To further clarify the influence of CMV infection on mortality, we reviewed autopsy reports of 50 patients. Among 15 patients with autopsy evidence of CMV disease, 14 had interstitial pneumonitis. Only one patient had lung CMV without evidence of interstitial pneumonitis. There were an additional ten cases of interstitial pneumonitis not associated with CMV, so CMV was a candidate pathogen in 58.8% of cases of interstitial pneumonitis. The distribution of CMV in autopsy tissues included lung (15 cases), liver (six), stomach (five), colon (four), small bowel (three), esophagus (two), adrenal (two), skin (two), rectum (one), and kidney (one). Nineteen patients included in this autopsy series had antemortem culture or biopsy evidence of CMV infection, and 15 of those patients had CMV demonstrable at autopsy. Of 31 patients who did not have antemortem evidence of CMV infection, no patient had CMV at autopsy.

DISCUSSION

The data obtained in this study reveal or confirm several important points regarding CMV infection after bone marrow transplantation: CMV is an important source of posttransplant mortality, and seropositive recipients are not protected against severe infection. To the contrary, recipient (but not donor) seropositivity is an important predictor of posttransplant CMV infection. Red cell and platelet transfusions may be a source of CMV infection, possibly leading to infection in as many as 20% of patients, although the exact role of this infectious source was not clear in our studies. As previously observed,[1,7] there appears to be an important relationship between AGVHD and CMV infection, although we failed to confirm the relationship between CMV and chronic GVHD reported by Lönnquist et al.[8]

Seropositive patients developed CMV infections nearly three times as frequently as seronegative patients after bone marrow transplantation. This parallels the findings of Meyers et al[7] that recipient (but not donor) seropositivity is strongly associated with CMV pneumonitis. This implies that reactivation of latent virus may be an important source of clinical infection. The studies on the molecular epidemiology of CMV infections recently reported by Winston et al[9] provide excellent evidence that pretransplant CMV exposure may result in CMV disease after transplant. In those studies, four patients with asymptomatic CMV excretion before transplant developed CMV infection after transplant. In each case the post–bone marrow transplant isolate was genetically identical to the pretransplant isolate. Although reactivation of CMV has not been rigorously proven in humans, other herpesviruses may be reactivated after latent periods.[10] In addition, immunosuppression similar to that used in bone marrow transplantation has resulted in CMV reactivation in murine models.[11] Apparent transmission of CMV by granulocytes from seropositive blood donors points to latent viruses harbored by such donors that become infective when transfused into immunosuppressed hosts.[12,13] Thus it is likely that seropositive bone marrow recipients reactivate viruses that are latent in one or more body tissues. The relative contribution of other sources, such as blood transfusions, in seropositive individuals is unclear.

The bone marrow donor was not an obviously important source of CMV, since donor serology did not predict risk for development of CMV. This is in contrast to the situation in solid organ transplantation, where the transplanted kidney[14] or heart[15] from a positive donor may carry the virus, causing infection and disease in the recipient. Our data imply that the bone marrow from a seropositive donor is less infective than the kidney or the heart. The explanation for this difference is not clear. The infected cells may be quickly destroyed after bone marrow transplantation. Alternatively, during latency, the virus may not reside in the bone marrow in adequate numbers to be infective. It is also possible that the acquisition of CMV from other sources, such as blood products, may mask the contribution of the bone marrow donor, as suggested by the preliminary data of Bowden et al.[16]

Our finding that patients developing CMV infection received more transfusions before development of CMV suggests that red cell and platelet transfusions may transmit CMV in this population. Granulocyte transfusions have been clearly implicated in causing CMV infection after marrow transplant (Winston et al[12] and Hersman et al[13]). None of our patients received granulocyte transfusions. Yeager et al[17] reported that newborns receiving more than 50 pediatric blood units had a 24.4% incidence of CMV infection, but when infants received only screened CMV-negative blood products, 0/90 developed CMV infection. Preiksaitis et al,[15] in a much smaller study of cardiac transplant patients, found that using only CMV-seronegative blood products reduced the incidence of posttransplant CMV. The preliminary study of Bowden et al[16] also suggests that blood product screening is effective in preventing CMV in bone marrow transplant patients. These studies strengthen our impression that CMV is transmitted by red cell and platelet transfusions during the post-transplant course. The low incidence of CMV seropositivity in our blood donor population (30%) may in part explain our relatively low posttransplant CMV infection rate. A prospective study is now in progress in Minnesota to define the importance of blood transfusion in transmission of CMV infection after bone marrow transplantation.

The conditioning regimen used did not influence CMV infection rate. However, nearly all of our patients received radiation, either total body or total lymphoid. Among four patients who did not receive irradiation, no patient acquired CMV. Meyers et al[7] have emphasized that irradiation (even in low doses) predisposes to CMV pneumonitis. It is apparent from our patients that there is no difference between total body and total lymphoid irradiation as far as CMV risk. Our data complement those of Meyers in suggesting that irradiation (even in low doses) predisposes to CMV infection by enhancing immunosuppression rather than by damaging CMV target organs.

The nature of the relationship between GVHD and CMV infection is important. In our patients, GVHD usually preceded CMV infection. Although it is tempting to suggest that the immunosuppressive therapy used to treat GVHD allowed CMV infection, in fact, CMV infection was associated as much with AGVHD treated topically as with AGVHD treated with high-dose bolus methylprednisolone. These data suggest that the immunosuppression associated with AGVHD is more important than anti-GVHD immunosuppressive therapy in allowing reactivation of latent virus or dissemination of virus in newly infected patients. The alternative explanation that CMV infection predisposes to GVHD appears unlikely, since GVHD preceded CMV infection in most of our patients. CMV infections have been associated with a number of immunologic alterations, however, including reversal of the T4-T8 lymphocyte ratio,[18] alteration in cytotoxic T cell[19] and natural killer cell[20] activity, and enhanced expression of HLA-DR antigens.[21] In addition, increased rejection of renal allografts has been associated with the presence of CMV infection.[18,22] Thus CMV might enhance immune system reactivity, or it might alter the antigenicity of host tissues, thereby leading to an increased incidence of GVHD. If this is the case, prevention of CMV infection may decrease the incidence of GVHD. Indeed, Condie and O'Reilly observed a suggestive decrease in GVHD incidence when they prevented post-transplant CMV infection with prophylactic hyperimmune globulin.[23]

The sources of CMV infections appear to differ among bone marrow transplant patients. Seropositive patients may reactivate latent virus, while seronegative patients acquire CMV from exogenous exposure, possibly from blood transfusions. Immunosuppression caused by AGVHD appears to predispose to CMV infection. Our data suggest, however, that minimizing immunosuppressive treatment of GVHD may not decrease incidence of CMV infection, but that effective GVHD prevention may have an impact on CMV infection rates. Regardless of the source, CMV infections are frequently quite serious, with significant mortality and organ dysfunction. We are currently evaluating screened seronegative blood products for prevention of CMV infection in seronegative recipients at the University of Minnesota. Reactivation may be the primary source of CMV infections in seropositive patients; prophylaxis designed to kill or suppress reactivated virus may be necessary to prevent clinical CMV disease in seropositive recipients. Immunoglobulin with high anti-CMV titer or antivirals such as acyclovir, 9-[(2-hydroxy-1-(hydroxymethyl)ethoxymethyl]guanine, or leukocyte interferon may prove useful when administered prophylactically to high-risk patients. The effectiveness of various forms of prophylaxis against CMV infection is currently under study, and we are hopeful that effective prophylaxis will improve results from bone marrow transplantation.

CONCISE REPORT

Human Endothelial Cells Synthesize Protein S

By Daryl S. Fair, Richard A. Marlar, and Eugene G. Levin

Human umbilical vein endothelial cells were analyzed for the presence of prothrombin, factor VII, protein C, and protein S in culture supernatants and cell extracts using specific radioimmunoassays. Only protein S was detected. Conditioned medium from 24-hour cultures and cell lysates contained 21.7 ng/mL and 88.8 ng/10^7 cells of protein S, respectively. Intrinsic labeling and immunoprecipitation indicated that protein S was synthesized and secreted as a 75,000 molecular weight protein. Vitamin K, phorbol myristate acetate, and thrombin increased the production or specific activity (determined from activity/antigen ratios of 0.99 to 1.07, 0.93 to 1.04, and 0.90 to 1.04, respectively) of protein S. While untreated cells secreted a partially active protein S (activity/antigen = 0.40), warfarin greatly decreased the specific activity (<0.10) of this molecule, suggesting that endothelial cells contain the enzymes required for the carboxylation of selected glutamic acid residues. The production of protein S by these cells supports the hypothesis that cofactor production and expression by the endothelial cells may play a significant regulatory role in the initiation, propagation, and suppression of hemostasis and thrombosis.

© 1986 by Grune & Stratton, Inc.

AMONG THE CELLULAR elements within the vasculature, platelets and endothelial cells have been implicated as principle components in the initiation, propagation, and suppression of hemostasis and thrombosis. One mechanism used by these cells is the synthesis or storage of specific proteins that amplify coagulation on their surfaces. Platelets store and release high molecular weight (mol wt) kininogen,[1,2] von Willebrand's factor[3] and factor V,[4,5] all of which are involved in clot formation or platelet aggregation. Recently, protein S has been found within platelets,[6] suggesting that these cells may also be responsible for limiting coagulation by the protein S-enhanced inactivation of factors Va and VIIIa by activated protein C.

Endothelial cells have also been shown to be a site for the initiation and propagation of coagulation.[7–10] In addition, these cells are unique in that they synthesize and express most of the cofactor activities associated with the activation and regulation of clotting. Among these components are tissue factor,[7,8] von Willebrand's factor,[11] factor VIII,[12] factor V,[13] high mol wt kininogen,[14] and thrombomodulin.[15]

We hypothesized that one of the general biological functions of endothelial cells is to control hemostasis and thrombosis by the production and expression of the cofactors that amplify these activities. Because protein S is a cofactor for activated protein C,[16] we tested our supposition by investigating the synthesis of this molecule by these cells. In this report, we demonstrate that human umbilical vein endothelial cells synthesize and secrete protein S, which can be modulated by warfarin and vitamin K. Thus this finding supports our hypothesis that all of the known cofactors required for the initiation, propagation, and suppression of coagulation are produced by the endothelial cells.

MATERIALS AND METHODS

Endothelial cells were isolated from human umbilical cord veins as previously described[17] and grown to confluence in T-75 flasks precoated with 2 mg/mL calf skin gelatin (Eastman Kodak Co, Rochester, NY). Cells were grown in RPMI 1640 supplemented with 20% fetal bovine serum (Reheis Co, Phoenix), 100 U/mL penicillin, and 100 μg/mL streptomycin (GIBCO, Grand Island, NY). Conditioned medium containing protein S was collected in RPMI 1640 in the absence of serum for 24 hours. In selected experiments, the cells were treated with phorbol myristate acetate (PMA, 400 ng/mL; Sigma Chemical Co, St Louis), alpha-thrombin (1 U/mL, a gift from Dr John Fenton, New York Department of Health, Albany), vitamin K_1 (AquaMEPHYTON; Merck, Sharp & Dohme, West Point, PA; 10 μg/mL) or warfarin [3(α-acetonyl benzyl)-4-hydroxycoumarin; Sigma; 1 μg/mL] for 16 to 24 hours in RPMI 1640 containing 0.1% bovine serum albumin.

Protein S was purified from plasma by the method of Dahlback [18] Measurement of protein S antigen was by either a double antibody competitive equilibrium radioimmunoassay[19] on undiluted samples or a Laurell electroimmunoassay with Coomassie staining[20] on culture supernatants concentrated 20-fold and dialyzed by ultrafiltration using an Amicon device (Amicon Corp, Danvers, Mass). Recovery of protein S was 80% to 85% as estimated, using iodinated protein S added before concentration. Activity was quantitated by a modification of the method of Comp et al,[21] where Russell's viper venom (1:4,000 dilution; Sigma) was used in place of pure factor Xa. The sensitivity of the assay was to 3% of normal human plasma with a precision of 7% to 10% within and between assays. Dilutions of normal plasma and purified protein S were used to construct standard curves for activity and antigen measurements. The values were expressed as a percentage of a normal plasma pool.

Cultures of confluent endothelial cells were washed with 4 mL of methionine-free minimal essential medium (Irvine Scientific, Santa Ana, Calif) and incubated in 4 mL of the same medium supplemented with 5 μg/mL vitamin K and 150 μCi/mL ^{35}S-methionine (Amersham Corp, Arlington Heights, Ill) for six hours at 37 °C.

After incubation, the supernatant was clarified by centrifugation at 100,000 g for 45 minutes at 4 °C, and the cell lysates were collected in 2 mL of 0.1% Triton X-100 (Eastman Kodak) containing 10 mmol/L benzamidine (Sigma), 1 mmol/L ethylamine diamine tetraacetic acid (EDTA), and 100 U/mL Trasylol (Bayer, Leverkusen, West Germany). Bovine serum albumin (5 mg/mL) was added to both the supernatant and cell lysate and immunoprecipitated using rabbit anti-protein S and *Staphylococcus aureus* exactly as described previously.[22] The immune complexes were solubilized into 2% sodium dodecyl sulfate (SDS) and electrophoresed on SDS-9% polyacrylamide slab gels containing ^{14}C-protein standards (New England Nuclear Corp, Boston) in the presence of 1% 2-mercaptoethanol.[23] Gels were fixed in 10% acetic acid, 25% methanol for one hour, washed extensively with water, incubated with 1 mol/L sodium salicylate for 30 minutes, dried, and subjected to autoradiography.

RESULTS

The production of protein S and other vitamin K-dependent proteins by human endothelial cells was analyzed by using specific radioimmunoassays for prothrombin, factor VII, protein C, and protein S. Only protein S was detected in significant quantities, with 88.8 ± 17.3 ng in the cell lysates from about 1×10^7 cells. Conditioned medium from 24-hour cultures contained 21.7 ± 3.3 ng protein S per milliliter, but none of the other molecules. Thus, of the four vitamin K-dependent proteins tested, only the molecule with cofactor activity was observed within the limits of this analysis.

To demonstrate that the endothelial cell synthesized protein S, we cultured the cells for six hours in the presence of radioactive methionine and immunoprecipitated both the supernatants and cell extracts with antibodies to protein S. We analyzed these cells for the production of von Willebrand's factor as control. Figure 1 is a representative example of five experiments in which the supernatant from endothelial cells was immunoprecipitated with rabbit anti-protein S in the absence and presence of 50 μg of exogenous purified protein S. A unique band of 75,300 ± 2,100 mol wt was precipitated with the antibody but was absent when unlabeled protein S was added to the supernatant before immunoprecipitation. The migration of this band was identical to iodinated native protein S (data not shown). Protein S represented about 0.1% of the total secreted protein relative to total trichloroacetic acid precipitable counts. Visualization of protein S in cell lysates was obscured by the coprecipitation of a nonspecific protein with a similar mol wt. When antibodies to von Willebrand's factor were used, the characteristic polypeptide chains of >220,000 daltons were observed (data not shown). Thus human endothelial cells synthesize and secrete protein S.

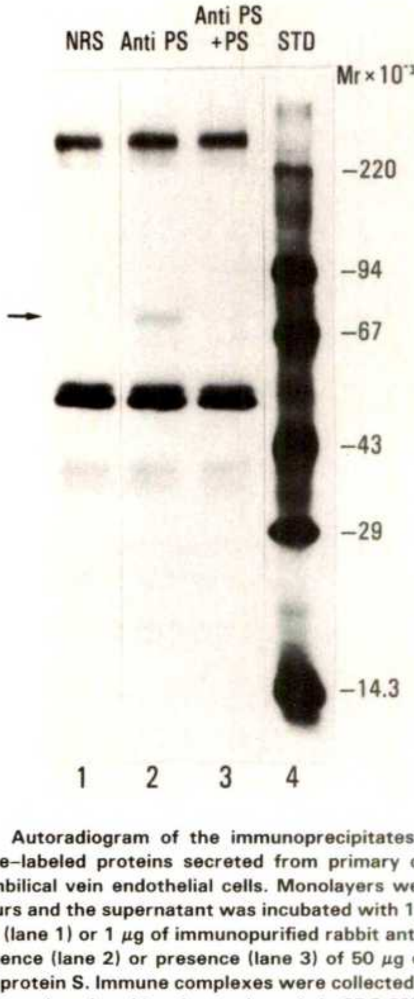

Fig 1. Autoradiogram of the immunoprecipitates from ^{35}S-methionine–labeled proteins secreted from primary cultures of human umbilical vein endothelial cells. Monolayers were labeled for six hours and the supernatant was incubated with 1 μg normal rabbit IgG (lane 1) or 1 μg of immunopurified rabbit anti-protein S in the absence (lane 2) or presence (lane 3) of 50 μg of purified, unlabeled protein S. Immune complexes were collected by binding to *S aureus* and analyzed by electrophoresis in SDS-9% polyacrylamide slab gels in the presence of 1% 2-mercaptoethanol. The migration of the labeled protein S-specific band is indicated by the arrow. Standards (lane 4) were myosin (220,000), phosphorylase b (94,000), bovine serum albumin (67,000), ovalbumin (43,000), carbonic anhydrase (29,000), and lysozyme (14,300).

The production of protein S from these cells implies that they may contain the carboxylase enzyme system required for the characteristic posttranslational modification of selected amino-terminal glutamic acid residues.[24] To investigate this possibility, we tested the effect of warfarin, vitamin K, thrombin, and PMA on the ability of these cells to produce functional molecules. Confluent cells were cultured for 24 hours in the absence or presence of these agents, and the secreted protein S was assayed for activity and antigen using both normal plasma and purified protein S for standard curves (Table 1). Neither the medium or medium containing PMA in the absence of cells had protein S activity or antigen. Cells cultured in medium only released a partially active protein S as judged by the activity/antigen ratios of 0.35 to 0.40. Addition of thrombin did not increase the production of protein S significantly, but the functional capacity of the molecule was greater, as indicated by the increase in the activity/antigen ratio of 0.90 to 1.04. Both PMA and vitamin K enhanced the accumulation of protein S, which had specific activities of 0.93 to 1.04 and 0.99 to 1.07, respectively. Warfarin decreased the secretion of protein S slightly, but demonstration of a functional molecule was below the limits of detection in our bioassay. These trends were observed in three separate experiments. Within the sensitivity of our assay methods, the production of functionally active protein S can be increased by vitamin K, PMA, and thrombin and is significantly decreased by warfarin, a known inhibitor of the carboxylation reaction.

Table 1. Modulation of Protein S Activity and Antigen Secreted From Human Endothelial Cells

Culture Supernatant	Protein S					
	Activity		Antigen		Activity/Antigen	
	NHP	PS	NHP	PS	NHP	PS
RPMI	<3	<1	<3	<1	—	—
RPMI + PMA	<3	—	<3	—	—	—
Control CM	14	3.3	35	9.5	0.40	0.35
PMA CM	51	22.2	49	23.8	1.04	0.93
Thrombin CM	35	15.0	39	14.4	0.90	1.04
Vitamin K CM	48	20.0	45	20.2	1.07	0.99
Warfarin CM	<3	<1	29	12.1	<0.10	<0.10

Confluent cultures of human umbilical vein endothelial cells were incubated in the presence of phorbol myristate acetate (PMA, 400 ng/mL), alpha-thrombin (1 U/mL), vitamin K (10 μg/mL), or warfarin (1 μg/mL) diluted in serum-free medium containing 0.1% bovine serum albumin. Condition medium (CM) from 24-hour cultures were collected and concentrated 20-fold before analysis for activity and antigen. Activity and antigen values are the means for two experiments and are expressed as percentages of pooled normal human plasma assuming protein S concentration in plasma was 29 μg/mL. Standard curves for activity and antigen measurements were based on dilutions of normal human plasma (NHP) or purified protein S (PS).

DISCUSSION

Synthesis of vitamin K-dependent blood coagulation proteins was once thought to be restricted to hepatocytes. Indeed, our lab has demonstrated that a human hepatoma cell line can produce most of these molecules, including protein S, which represent their plasma protein counterparts immunochemically, structurally, and functionally.[22,25] Recently, the human monocyte and macrophage have been demonstrated to synthesize factor VII.[26,27] In this report, we have shown that the endothelial cell has the capacity to synthesize and secrete protein S, which has a similar mol wt as the plasma form,[19,28] and that its synthesis and activity can be affected by known pharmacologic modulators of vitamin K-dependent proteins. The finding that vitamin K increases and warfarin decreases the synthesis and specific activity of protein S suggests that they contain the enzymes required for gamma carboxylation. Thus at least two additional cell types have the capacity to produce functionally active members of this protein family but appear to be limited or restricted to the synthesis of a particular component.

The increase of protein S levels after thrombin addition would be physiologically consistent with the role of thrombin in protein C activation.[15] It can be envisioned that the increase in activated protein C mediated by thrombin–thrombomodulin would necessitate an increase in protein S levels to attain maximum protein C activity. The simultaneous occurrence of increased protein S-activated protein C levels could be coordinated by one endothelial cell. Studies determining the course of protein S release and the role thrombomodulin might play in protein S release will help to clarify the link between activation of protein C and protein S release.

The synthesis of protein S by endothelial cells may be biologically significant. Patients undergoing warfarin therapy show a decrease in vitamin K-dependent proteins, including protein S, of about 50%[19]; however, individuals with liver disease show a discordant reduction in protein S (~25% decrease) relative to protein C (~50% reduction), suggesting that there is another site of synthesis for protein S.[29] Our studies indicate the endothelium as a likely source of this molecule and would explain this apparent discrepancy. Recently, Stern et al[30] have shown that the endothelium can serve as a functional surface for the assembly of the activated protein C–protein S complex. In addition, they have evidence for the internalization of protein S by these cells in the absence of activated protein C, but protein S remains surface associated in its presence.[31] Our data suggest that the endothelial cell constitutively synthesizes and secretes protein S, and internalizes this molecule in a dynamic manner. Once low levels of activated protein C are formed by thrombin–thrombomodulin on the endothelial surface,[15] it may be in proximity to protein S (receptor), resulting in the formation of an active, stable inactivator complex for factors VIIIa and Va. The demonstration that this cofactor of activated protein C activity is produced by this cell supports our original hypothesis that cofactor production and expression by the endothelial cells may play a significant regulatory role in the initiation, propagation, and suppression of hemostasis and thrombosis.

ACKNOWLEDGMENT

We thank Marsha McDonald and David Revak for excellent technical assistance and Joy Lozano and Ellen Schmeding for preparation of the manuscript. We thank Drs David M. Stern and Peter P. Nawroth for providing preprints of their manuscripts.

CONCISE REPORT

Hyperacute Graft-v-Host Disease in Patients Not Given Immunosuppression After Allogeneic Marrow Transplantation

By K.M. Sullivan, H.J. Deeg, J. Sanders, A. Klosterman, D. Amos, H. Shulman, G. Sale, P. Martin, R. Witherspoon, F. Appelbaum, K. Doney, P. Stewart, J. Meyers, G.B. McDonald, P. Weiden, A. Fefer, C.D. Buckner, R. Storb, and E.D. Thomas

Sixteen patients with leukemia in relapse or second to third remission, 5 to 27 years old (median, 17), were given cyclophosphamide (60 mg/kg × 2) and total body irradiation (2.25 Gy for each of seven days) followed by unmodified marrow grafts from HLA-identical siblings. Patients did not receive posttransplant immunosuppression and were followed a median of nine months (range, 5–17). Prompt engraftment was sustained in 12 patients with a median time of 16 days (range, 10 to 63) to achieve 500 neutrophils/mm^3. One patient failed to engraft, one had delayed engraftment, and two had late poor graft function. All 15 with engraftment developed moderate to life-threatening graft-*v*-host disease (GVHD, eight grade II and seven grade III-IV). This syndrome was hyperacute (median onset eight days [range, 7 to 29] posttransplant) and manifest by severe skin disease (14 patients at stage 3 and one at stage 4), fever (ten patients), and liver (four patients, stage 3-4) or gut (four patients, stage 3-4) involvement. Serial tissue biopsies confirmed acute GVHD in 13 of 15 patients. Ten were treated with antithymocyte globulin and cyclosporine (four survive), and four with corticosteroids (two survive). Actuarial survival to 17 months was 37%. Causes of death included interstitial pneumonia (four), infection (three), graft failure (one), venocclusive disease (one), and relapse of leukemia (one). Age-matched controls receiving standard methotrexate after transplant had comparable relapse-free survival but only a 25% incidence of grade II-IV acute GVHD ($P < .0001$). We conclude that deleting posttransplant immunosuppression is associated with frequent and severe hyperacute GVHD, infectious complications, and occasional poor graft function.

ACUTE graft-*v*-host disease (GVHD) and associated infection and interstitial pneumonia (IP) remain major determinants of morbidity and mortality following HLA-identical marrow transplantation. Demonstration that GVHD could be averted or modified in animals if immunosuppressive agents such as methotrexate (MTX), cyclophosphamide (CY), or cyclosporine (CsA) were given after transplant led to direct clinical application.[1-4] However, immunosuppressive agents may contribute to delayed engraftment, IP, or infection and might not always be needed in humans. Moreover, previous clinical trials comparing different prophylaxis regimens could be invalidated if compared agents were equally ineffective in preventing GVHD.

The first study deleting immunosuppression after allogeneic transplant reported no difference in incidence or severity of acute GVHD in patients who did or did not receive MTX.[5] However, MTX recipients appeared to have more GVHD than expected for their age. Based upon these findings, it seemed justified to study young patients not given immunosuppression after marrow grafting. We report the incidence and severity of GVHD, IP, and infection in this trial and compare results with age-matched historic controls who differed only by receiving standard MTX.

MATERIALS AND METHODS

From March 1984 to March 1985, 16 study patients <30 years of age did not receive posttransplant immunosuppression. Protocols and consent forms were approved by the Institutional Review Board of the Fred Hutchinson Cancer Research Center. Attending physicians fully outlined the advantages and disadvantages of the procedure. Controls were derived from a randomized trial of patients less than age 30 conducted from Dec 1980 to July 1984 comparing standard MTX to other MTX-based regimens.[6] A total of 44 patients in that trial received standard intravenous (IV) MTX, 15 mg/m^2 day 1 and 10 mg/m^2 days 3, 6, and 11, then weekly to day 102.[2]

Patient characteristics are shown in Table 1. Patients in both groups received CY (60 mg/kg × 2), followed by 15.75 Gy total body irradiation (TBI, 2.25 Gy daily × 7). Both groups were comparable for factors influencing GVHD[7] and received unmodified marrow from HLA-identical siblings.[2] Engraftment was confirmed by peripheral counts, marrow aspirates, and cytogenetic markers. The assessment, grading, and treatment of acute and chronic GVHD have been described.[2,8] Grade II-IV acute GVHD was treated with prednisolone (2 mg/kg/d) or antithymocyte globulin (ATG, 15 mg/kg × 3) and CsA (3 mg/kg/d IV or 12.5 mg/kg/d orally).[9]

RESULTS

Engraftment. Engraftment was more rapid in those not receiving MTX (Table 2). Only one patient failed to engraft: due to electrocardiographic abnormalities, she received only 60 mg/kg CY followed by 15.75 Gy TBI. Three others not receiving immunosuppression had graft problems: one had delayed myeloid and platelet recovery despite early GVHD

No. of patients	16	44
Patient age		
Median (range) in years	17 (5–27)	19 (1–29)
No <10 yr old	4 (25%)	10 (22%)
Patient sex (M/F)	9/7	27/17
Patient–donor sex mismatch	9 (56%)	24 (55%)
Diagnosis		
Refractory ANL/ALL	1/0	1/0
Relapse ANL/ALL	3/1	11/12
2nd-3rd remission ANL/ALL	2/7	0/6
CML acceleration/blast crisis	1/1	3/9
Lymphoma	0	2
Median (range) no. of marrow cells infused ($\times 10^{-8}$/kg)	2.6 (1.2–5.1)	2.2 (0.9–11.5)
Median (range) follow-up in months	9 (5–17)	32 (14–56)

MTX, methotrexate; ANL, acute nonlymphoblastic leukemia; ALL, acute lymphoblastic leukemia; and CML, chronic myelogenous leukemia.

(63 days to 500 neutrophils/mm^3) and two had late graft failure after acute GVHD development.

Hyperacute GVHD. All 15 study patients who engrafted developed grade II-IV acute GVHD (Table 2). The onset was hyperacute (median, day 8) and associated with stage 3-4 skin disease (generalized erythroderma or desquamation) in all 15 patients. Fever ≥40 °C accompanied the onset in ten patients. Hepatic and enteric GVHD developed in most patients but was less severe than the dermal component: four had stage 3-4 liver disease (bilirubin ≥6 mg/dL) and four had stage 3-4 gut disease (diarrhea ≥1,500 mL/d, severe pain or ileus). Although difficult to distinguish between early GVHD and the histologic effects of chemoradiotherapy,[10] serial skin, liver, or gut biopsies confirmed GVHD in 13 patients. Treatment of hyperacute GVHD was started eight to 22 days (median, day 10) after transplant; ten patients received ATG and CsA (four survive) and four received corticosteroids (two survive). Six had sustained response, four had no benefit, and four had response followed by GVHD flare on tapering therapy.

Table 2. Posttransplant Regimen and Course

Factor	Posttransplant Regimen	
	No Immunosuppression	Standard MTX
No. of engrafted patients	15	44
Median (range) day to 500 neutrophils/mm^3	16 (10–63)	24 (17–35)
Median (range) day to last platelet transfusion*	45 (12–131)	32 (16–92)
Overall grade acute GVHD		
0 (None)	0	22
I (Mild)	0	12
II (Moderate)	8	1
III-IV (Severe, life-threatening)	7	9
Onset grade I-IV acute GVHD

No. with interstitial pneumonia	4 (27%)	9 (20%)
No. with relapse of leukemia	1 (7%)	13 (30%)
No. with chronic GVHD/total no. surviving ≥180 days	2/6 (33%)	9/27 (33%)

MTX, methotrexate.

*Among patients surviving ≥85 days. Day 0 is the day of transplant.

Fig 1 depicts the incidence and time to onset of GVHD. Patients receiving MTX had a 25% incidence of grade II-IV acute GVHD compared with 100% incidence in those not given immunosuppression ($P < .0001$).

Infection and survival. Six of 16 study patients developed bacteremia, two cytomegalovirus (CMV) viremia, one aspergillus pneumonia, one toxoplasmosis, and one fulminant hepatic varicella. Four had IP (two pneumocystitis, one CMV, and one idiopathic) and three had hepatic venocclusive disease (VOD). Chronic GVHD developed in two of six surviving ≥180 days. Four study patients died of IP, three of infection, and one each of graft failure, VOD, and relapse. Fig 2 presents actuarial survival. Although relapse-free survival was comparable in study patients and controls, death from nonrelapse causes was increased in the no immunosuppression group ($P = .067$).

DISCUSSION

Based upon controlled studies in experimental animals, patients have routinely received posttransplant immunosuppression to prevent or ameliorate GVHD. The efficacy and toxicity of prophylaxis are incompletely understood since few patients have not received immunosuppression after transplant. We selected young patients with advanced leukemia for this pilot study since there might be either no increase in GVHD if prophylaxis were deleted,[5] or a possible antileukemic benefit if GVHD were augmented.[11] If these pilot data suggested no additional hazard, we proposed a subsequent randomized trial comparing MTX and placebo.

We found, however, that deleting posttransplant immunosuppression was associated with development of grade II-IV

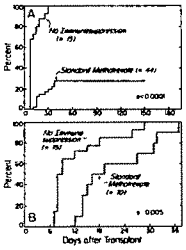

Fig 1. Kaplan-Meier estimates (generalized Wilcoxon test statistic). (A) Probability of developing grade II-IV acute GVHD. (B) Time to onset of grade II-IV acute GVHD. One patient in the no immunosuppression group failed to engraft and is excluded from analysis.

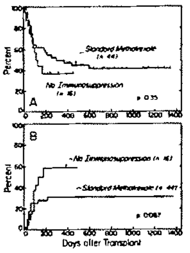

Fig 2. Kaplan-Meier estimates (generalized Savage test statistic). (A) Probability of relapse-free survival. Vertical marks represent patients surviving in remission as of Aug 1, 1985. The actuarial estimate of relapse of leukemia was 11% in the no immunosuppression group and 40% in the standard methotrexate group ($P = .27$). (B) Probability of death from nonrelapse (ie, transplant-related) causes. Patients are censored from analysis at the time of relapse.

GVHD in all 15 patients who achieved engraftment. This hyperacute syndrome included severe skin disease and fever beginning seven to 14 days after transplant. Features were sufficiently severe to require prompt treatment. Although response was often dramatic and perhaps blunted development of severe liver and gut involvement, GVHD flare was observed when therapy was tapered in four of ten who initially responded. Survival was poor with most deaths resulting from IP or infection. In contrast to others,[5,12] we noted an equal incidence of IP in those who did and did not receive MTX. Any lessening of pulmonary toxicity in patients not given MTX may be offset by increased GVHD and associated immunodeficiency.[13]

Age-matched controls given the same CY and TBI preparation and standard MTX after transplant had a 25% incidence of grade II-IV acute GVHD.[6] This agrees with other reports of infrequent GVHD in young patients receiving MTX[14,15] but differs from the study by Lazarus et al where 24 of 34 patients (71%) (median age, 12 years) given standard MTX developed grade II-IV acute GVHD.[5] The high incidence in the MTX controls may explain why that study found no increase in GVHD in 21 patients not given MTX.

The development of graft problems in four of our 16 study patients was not expected. One patient given a reduced dose of CY failed to engraft despite 15.75 Gy TBI. Three developed severe early GVHD with either delayed myeloid recovery or poor late graft function. We have observed such "lymphoid" grafts in GVHD patients who required marrow reinfusion to correct poor myeloid and platelet recovery.[16] Alternatively, deleting posttransplant immunosuppression could encumber engraftment. Studies in dogs suggested that MTX facilitated engraftment but the mechanism of the effect was never clear.[17]

The present data would refute the theory that previous trials of single agent prophylaxis were ineffective in preventing GVHD. Moreover, both animal[18] and clinical studies[14] have reported a reduction in the incidence of GVHD when multiagent immunosuppression was given after transplant. A recent trial comparing CsA to a combination of CsA and MTX showed both a reduction in GVHD and an increase in survival in patients receiving combination prophylaxis.[19] Such studies illustrate the interrelationship of graft function, GVHD, immunosuppression, IP, infection, and survival following allogeneic transplant. We conclude from the present study that deleting posttransplant immunosuppression is associated with frequent and severe hyperacute GVHD. Elimination of MTX does not appear to prevent IP or infectious complications. Occasional poor graft function may result from deletion of posttransplant immunosuppression, development of GVHD, or other factors.

CONCISE REPORT

Cultured Human Endothelial Cells Synthesize a Plasma Membrane Protein Complex Immunologically Related to the Platelet Glycoprotein IIb/IIIa Complex

By O.C. Leeksma, J. Zandbergen-Spaargaren, J.C. Giltay, and J.A van Mourik

We have previously demonstrated that endothelial cells synthesize a plasma membrane protein indistinguishable from platelet glycoprotein (GP) IIa. The present study provides evidence for a further analogy between the platelet and the endothelial cell membrane by showing that cultured endothelial cells also synthesize a membrane protein complex immunologically related to the platelet GP IIb/GP IIIa complex. This evidence is based on the following observations: (1) C17, a murine monoclonal antiplatelet GP IIIa antibody, consistently precipitates two proteins, apparent molecular weights, respectively, 115,000 and 125,000 reduced and 95,000 and 135,000 nonreduced, from metabolically (^{35}S-methionine) as well as surface ^{125}I-labeled cultured human endothelial cells; (2) upon crossed immunoelectrophoresis of solubilized endothelial cells against a polyclonal rabbit antiplatelet antiserum and ^{125}I-labeled C17 IgG, a single precipitate of the protein(s) recognized by C17 is observed. As judged by their mobility in 9% polyacrylamide gels, both endothelial proteins appear to have a somewhat larger molecular weight than their platelet counterparts. Patterns obtained by crossed immunoelectrophoresis are also indicative of a difference in electrophoretic behavior of the platelet GP IIb/IIIa complex and the endothelial cell protein complex.

© 1986 by Grune & Stratton, Inc.

ALTHOUGH IT IS BELIEVED that several processes related to thrombosis and hemostasis occur at the endothelial cell surface, little is known at present about the composition and architecture of the endothelial cell membrane. Attempts in our laboratory to produce monoclonal antibodies specifically directed toward endothelial cell membrane components, which could serve as tools to study the role of such membrane constituents in endothelial cell function, yielded several antibodies that reacted with platelets as well.[1]

Evidence was obtained using these monoclonal antibodies that endothelial cells synthesize a plasma membrane protein indistinguishable from platelet glycoprotein (GP) IIa.[1] In view of this observation, monoclonal antibodies against platelet GPs were tested for their ability to react with cultured endothelial cells. Here we show that one of these antibodies, designated CLB C17, directed to platelet GP IIIa,[2] recognizes an endothelial cell plasma membrane protein complex immunologically related to the platelet GP IIb/IIIa complex. Possible implications of this finding in terms of endothelial cell (patho)physiology are discussed.

MATERIALS AND METHODS

Preparation of endothelial cells and platelets. Culture, surface labeling with ^{125}I, and metabolic labeling with ^{35}S methionine of umbilical vein endothelial cells was performed as described.[1] Platelets from normal volunteers and from a previously described patient (R.E.) with Glanzmann's thrombasthenia[1] were prepared and surface-labeled with ^{125}I as outlined elsewhere.[1,2]

Immunoprecipitation. Proteins were precipitated from lysates of endothelial cells or platelets by preformed complexes of monoclonal antibodies and goat antimouse IgG as described in detail elsewhere.[1,2]

Crossed immunoelectrophoresis Crossed immunoelectrophoresis (CIE) of Triton X-100–solubilized platelets (Merck, Darmstadt, FRG) and endothelial cells against a rabbit antiplatelet antiserum, prepared as described,[3] was carried out as in Van Mourik et al and Kunicki et al,[1,3] except that an intermediate gel containing labeled monoclonal antibody was used in the second dimension.[4] The identity of the endothelial cell antigens present in the immunoprecipitate observed by CIE was established by direct sodium dodecyl sulfate-polyacrylamide gel electrophoretic (SDS-PAGE) analysis of ^{125}I antigens contained in individually excised precipitates as described,[3] except that indirect immunofluorescence was used to locate the antigen(s) recognized by the monoclonal antibody To this end, Triton X-100–solubilized ^{125}I-labeled endothelial cells were analyzed by CIE using an intermediate gel containing unlabeled monoclonal antibody. Gels were washed extensively but not stained. Bound monoclonal antibody was detected by overlaying the plates with FITC-labeled goat antimouse IgG

Monoclonal antibodies. Antibodies C17, C15, and 6C9 have been reported on elsewhere.[2,5] The epitopes recognized by these monoclonals reside probably on GP IIIa, as suggested by crossed immunoelectrophoresis and immunoprecipitation experiments.[2,5] Immunoblotting experiments, performed to better define the specificity of these antibodies, have thus far met with little success, however. We cannot fully exclude presently therefore, that these antibodies recognize epitopes that are specific for the GP IIb/IIIa complex, as suggested by Newman et al.[6] Antibodies H1 and Nx133 were also prepared in our laboratory and are all directed to epitopes on the GP IIb/IIIa complex based on immunofluorescence and immunoprecipitation studies with normal as well as thrombasthenic platelets. Details as to their specificity and effect on platelet function will be reported elsewhere.

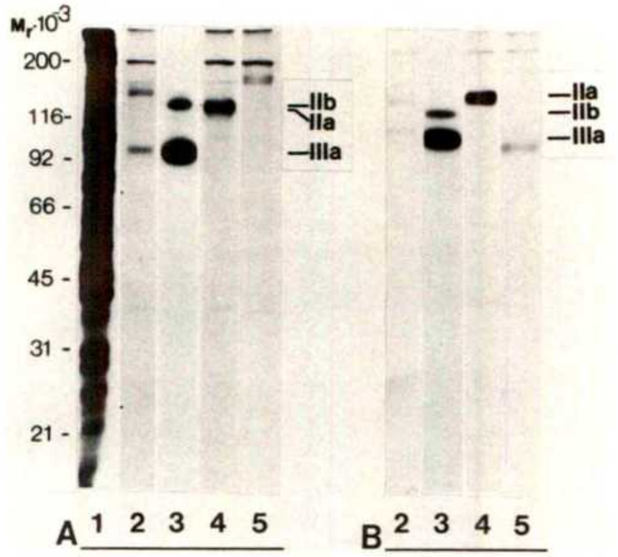

Fig 1. Immunoprecipitation of ^{35}S-methionine–labeled endothelial proteins with CLB-C17. Endothelial cells were cultured in the presence of ^{35}S-methionine for 24 hours as previously described.[1] Cell lysates were incubated with preformed complexes of monoclonal antibodies and goat anti-mouse immunoglobulins.[2] Washed ternary complexes were analyzed nonreduced (A) and reduced (B) by SDS-PAGE in 9% gels. Proteins were visualized by autoradiography. Lane 1, ^{35}S-methionine–labeled NP$_{40}$-solubilized endothelial cells. Lane 2, proteins precipitated with CLB-C17. For comparison, lane 3 shows ^{125}I-labeled IIb and IIIa precipitated with the same antibody from platelets; lane 4, ^{35}S-labeled IIa isolated with monoclonal antibody CLB-HEC 75[1]; and lane 5, an endothelial antigen precipitated by an endothelial cell-specific monoclonal antibody. (J.A. van Mourik et al, manuscript in preparation.)

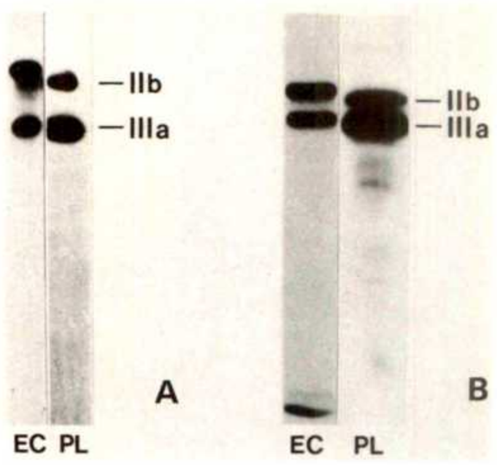

Fig 2. (A) Nonreduced and (B) reduced ^{125}I-labeled membrane proteins from endothelial cells (EC) and platelets (PL) recognized by CLB-C17. Endothelial cells and platelets were surface-labeled by the iodogen procedure, solubilized with NP$_{40}$, and incubated with complexes of antimouse IgG and CLB-C17. An autoradiogram of an SDS-PAGE (9%) analysis of the immunoprecipitates is shown.

RESULTS

Synthesis of a GP IIb/IIIa-like complex by cultured endothelial cells. Precipitation of GP IIIa from platelet lysates with monoclonal antibody C17 usually results in coprecipitation of GP IIb.[1,2] Incubation of lysates from either metabolically labeled (Fig 1) or surface-labeled (Fig 2) endothelial cells with preformed complexes of C17 and goat antimouse immunoglobulins also results in the precipitation of two labeled antigens that behave similarly to platelet GP IIb and IIIa upon SDS electrophoresis in 9% polyacrylamide gels under nonreducing and reducing conditions. Although it is apparent, especially in Fig 1, that other endothelial proteins have been trapped in the immunoprecipitate, the two proteins corresponding with platelets GP IIb and IIIa were specifically precipitated with antibody C17. The background pattern of trapped proteins was seen with other monoclonal antibody controls as well (Fig 1, lanes 4 and 5). However, the two bands representing endothelial IIb and IIIa were not observed in these control lanes. Furthermore, precipitation of the proteins of interest was prevented by the addition of unlabeled platelet lysate to the precipitation reaction (not shown). The metabolic labeling of GP IIb/IIIa was always less intense than that of GP IIa. Results from preliminary experiments (not shown) suggest that this is due to the fact that endothelial cells have more GP IIa than GP IIb/IIIa molecules on their surface.

CIE of solubilized endothelial cells. Upon CIE of solubilized platelets against a polyclonal rabbit antiplatelet antiserum and ^{125}I-labeled C17 IgG, the most predominant immunoprecipitation arc containing the GP IIb/IIIa complex (Fig 3A) can be visualized by autoradiography (Fig 3B). When an identical analysis is performed using an endothelial cell lysate, autoradiography also reveals a single radiolabeled precipitate (Fig 3C). This antigen has a lower mobility as compared with that of the platelet IIb/IIIa complex (Fig 3D). In contrast to what was observed for the platelet GP IIb/IIIa complex,[5] CIE patterns of the endothelial GP IIb/IIIa complex were unaffected by EDTA (not shown). The identity of the endothelial precipitate was established by SDS-PAGE analysis of the precipiated proteins (Fig 3E).

DISCUSSION

We have previously shown that endothelial cells and platelets share a membrane protein indistinguishable from platelet GP IIa.[1] Recently, Thiagarajan et al demonstrated that cultured endothelial cells also synthesize a platelet GP IIIa-like protein.[7] Using an immunoaffinity chromatography technique, which consistently resulted in the precipitation of GP IIb and IIIa from platelets, they were unable, however, to isolate GP IIb or another protein in stoichiometric amounts with this GP IIIa-like protein from endothelial cell lysates and therefore suggested that endothelial GP IIIa might not be complexed with a GP IIb-like protein. The present study does provide evidence that cultured endothelial cells synthesize a membrane protein complex, which appears to be similar to the platelet GP IIb/IIIa complex. Immunoprecipi-

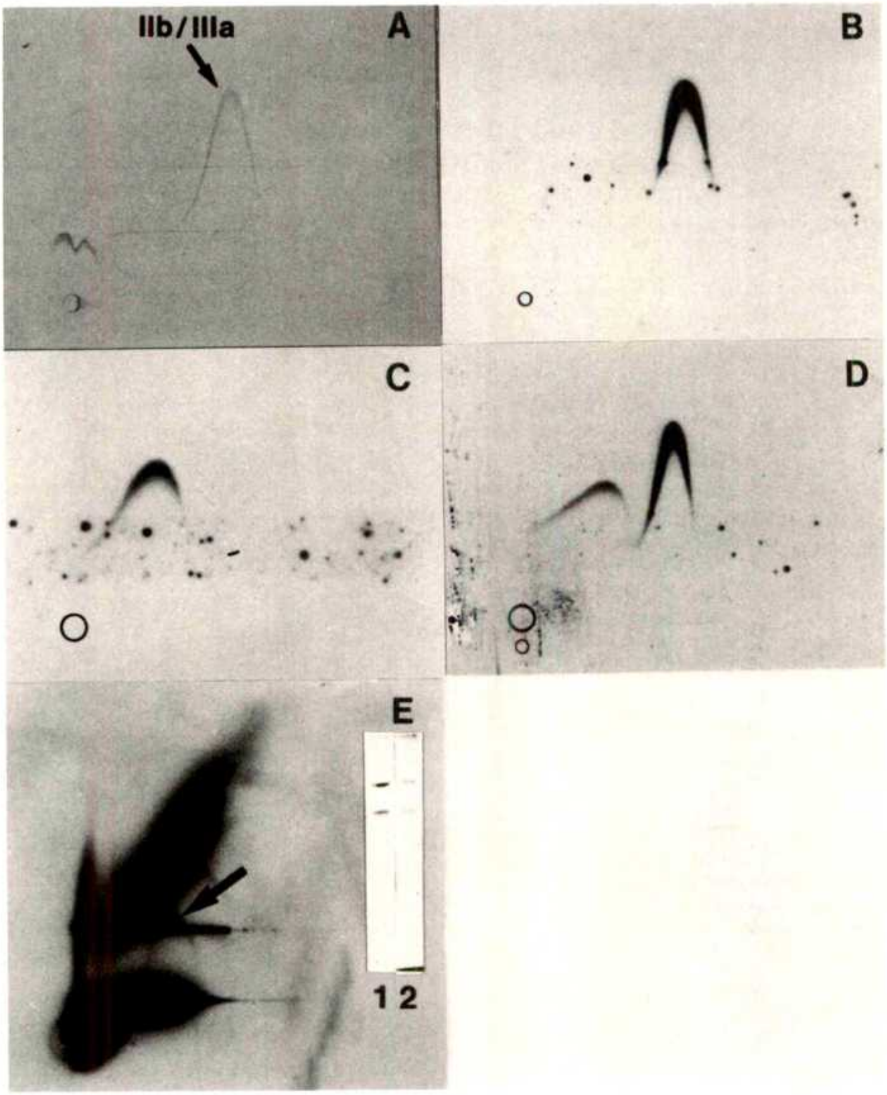

Fig 3. Crossed immunoelectrophoresis of Triton X-100–solubilized platelets and endothelial cells. Samples (equivalent to 1.5 × 10^7 and 2 × 10^6 cells, respectively) were electrophoresed in first-dimension gels containing 0.5% Triton X-100, and then in the second dimension against 0.85% (vol/vol) of a rabbit antiplatelet antiserum in the upper gel and ^{125}I-labeled CLB-C17 IgG in the intermediate gel. Slides were stained with Coomassie brilliant blue and subsequently subjected to autoradiography. (A) Coomassie stain of platelets. (B) Autoradiogram of (A). (C) Autoradiogram of endothelial cells. (D) Autoradiogram of platelets and endothelial cells (same amount of lysate of platelets and endothelial cells as applied in (B) and (C), respectively) run together on one plate. (E) Autoradiogram of ^{125}I-labeled endothelial cells. The location of the IIb/IIIa complex is indicated by a thick arrow. Inserts show an analysis by SDS-PAGE (9% gel, nonreduced) of the excized region encompassing the peak of the IIb/IIIa complex precipitate (lane 2). Lane 1 shows, for comparison, the proteins isolated from the same endothelial cell lysate by ordinary immunoprecipitation with antibody C17. Open circles indicate application wells (not visualized by autoradiography).

tation of GP IIIa with monoclonal C17 from endothelial cell lysates always resulted in the appearance of apparently stoichiometric amounts of GP IIb-like material in the precipitate. Furthermore, CIE experiments pointed toward the presence of a GP IIb/IIIa-like complex, which was recognized by a polyclonal rabbit antiplatelet antiserum. The precipitate obtained with this polyclonal antiserum could be radiolabeled by adding radiolabeled IgG of the nonprecipitating monoclonal C17 to the intermediate gel. These observations suggest that the platelet and the endothelial cell proteins share several epitopes.

Immunoprecipitation and CIE studies indicate that endothelial cells contain relatively little GP IIb/IIIa as compared with platelets, which is in keeping with the reported 100,000 GP IIIa-binding sites per endothelial cell.[7] In agreement also with the observation of Thiagarajan et al on endothelial GP IIIa,[7] endothelial and platelet GP IIb/IIIa appear to differ antigenically. We observed that only one, C17, of the five monoclonal antibodies against platelet IIIa or the IIb/IIIa complex (C17, C15, H1, 6C9, NX133) developed in our laboratory reacted with endothelial cells as judged by CIE. Immunoprecipitation studies suggest some reactivity of C15 with labeled endothelial cell proteins as two faint bands corresponding with the material precipitated by C17 were seen on autoradiograms of SDS-PAGE of C15 precipitates. The present study allows no conclusions as to the nature of these antigenic differences. Endothelial GP IIIa was suggested to have a slightly larger molecular weight than its platelet counterpart.[7] Our SDS 9% PAGE experiments point toward a similar difference for endothelial GP IIb. Furthermore, immunoprecipitation with C17 in the presence of EDTA at a high pH did not result, in contrast to what was observed with platelets,[2,5] in a preferential precipitation of GP IIIa. The C17 antigen from endothelial cell and platelet lysates also showed a difference in mobility as examined by crossed immunoelectrophoresis. To exclude that this difference was due to the presence of only endothelial GP IIIa within the endothelial precipitate, precipitation arcs obtained with ^{125}I-labeled endothelial cell lysates were excised and analyzed by SDS-PAGE.[3] Autoradiograms revealed the presence of both endothelial GP IIb and GP IIIa.

The observed differences between platelet and endothelial GP IIb/IIIa are not explained by the present study; it is an issue that clearly deserves further study as it may have considerable bearing on our conceptual idea regarding the role of endothelial GP IIb/IIIa in human (patho)physiology. For instance, in Glanzmann's thrombasthenia, platelets are deficient in glycoproteins IIb/IIIa,[8-10] the presence of an identical GP complex on endothelial cells could imply that this disorder is in fact an "endotheliopathy" as well. Since anti-IIb/IIIa antibodies have been observed in autoimmune thrombocytopenias,[11-13] the question whether such antibodies may also react with endothelial GP IIb/IIIa and perhaps contribute to the pathogenesis of petechiae in some of these patients is equally intriguing. Although binding of fibrinogen to endothelial cells has been observed,[14-16] additional functional studies will have to reveal whether endothelial GP IIb/IIIa indeed acts like platelet GP IIb/IIIa as a receptor for fibrinogen, von Willebrand factor, and fibronectin.[17-22] The answer to these questions, which are currently addressed in our institute, could lead to a better understanding of the nature of the endothelial GP IIb/IIIa complex.

NOTE ADDED IN PROOF

While this manuscript was under review, Fitzgerald et al[23] also reported the synthesis by human endothelial cells of membrane glycoproteins similar to platelet membrane GP IIb and IIIa.

ACKNOWLEDGMENT

The authors gratefully acknowledge Drs A.E.G. Kr. von dem Borne and M. Hamers for their constructive criticism and careful review of this manuscript.

CONCISE REPORT

A New Translocation, t(10;14)(q24;q11), in T Cell Neoplasia

By Ian D. Dubé, Susana C. Raimondi, David Pi, and Dagmar K. Kalousek

Four cases of T cell neoplasia are reported: three presenting as T cell acute lymphoblastic leukemia and one presenting in the leukemic phase of a T cell lymphoma. In all cases, the cells of the leukemic clone were characterized by an identical cytogenetic abnormality. This abnormality was a unique reciprocal translocation involving chromosomes 10 and 14. The breakpoint in chromosome 14 was in band q11, coincident with the assigned locus of the α-chain gene of the T cell antigen receptor. The breakpoint in chromosome 10 was in band q24, a region reported to include the locus of the terminal deoxynucleotidyltransferase (TdT) gene. Our observations suggest that translocation t(10;14)(q24;q11) is specific for T cell neoplasia and that a gene in chromosomal band 10q24, possibly the TdT gene, plays an important role in T cell neoplasia when its expression or coding sequence is altered by aberrant recombination involving a T cell antigen receptor gene.

© 1986 by Grune & Stratton, Inc.

EARLY CYTOGENETIC STUDIES in human cancer resulted in the identification of chromosomal changes that were specific for certain abnormal clonal proliferations (eg, Ph^1 in CML).[1] With the advent of improved cytogenetic techniques and better characterization of malignant cells, it became apparent that some cytogenetic changes were clearly of diagnostic[2] and more recently, prognostic[3] value. When molecular genetic techniques were used to investigate the basis of these cytogenetic changes, proto-oncogenes and "hotspots" for recombination were discovered at several of the nonrandomly involved chromosomal regions.[4]

In those cancers characterized by specific reciprocal translocations, a general pattern has emerged in which the expression or coding sequence of a proto-oncogene near one of the translocation breakpoints is altered as a result of its juxtaposition to a sequence of actively transcribed DNA from the other breakpoint. Knowledge of this pattern has been utilized in the cloning and characterization of putative oncogenes when only one sequence (that of the actively transcribed DNA) was known.[5,6]

Recently, T cell antigen receptor genes have been characterized.[7,8] It is now evident that T cell antigen receptor diversity is facilitated by the recombination of subunits in different parts of the genome.[9] The α-chain gene of the T cell antigen receptor has been assigned to chromosomal band 14q11 to q13.[10] This region is considered to be a hotspot for genetic recombination in differentiating T cells and has been observed to be nonrandomly involved in chromosomal abnormalities in T cell neoplasia.[11,12] A fragile site has been observed at chromosomal band 10q25,[13] and the gene for human terminal deoxynucleotidyltransferase (TdT) has recently been localized to the region 10q23-q25.[14]

We have observed four cases of T cell neoplasia in which the cells of the leukemic clones had in common a specific translocation involving chromosome 10 in band q24 and chromosome 14 in band q11. Our observations suggest that a gene, or genes, important in T cell proliferation and/or differentiation resides in 10q24 and can play an important role in T cell neoplasia. We speculate that the TdT gene may be involved in these translocations, becoming deregulated or mutated when juxtaposed to the α-chain gene of the T cell antigen receptor.

MATERIALS AND METHODS

Patients. Four patients with t(10;14)(q24;q11) were identified in a collaborative study that included 136 cases from Memphis, 28 from Toronto, and 52 from Vancouver. The translocation was observed at diagnosis in two of 164 cases of childhood acute lymphoblastic leukemia (ALL), at relapse in one of 52 cases of adult ALL, and at bone marrow relapse in one case of adult T cell lymphoma from a series of sporadically studied lymphomas. Of the 164 cases of childhood ALL, 22 were T cell ALL. (Routine immunophenotyping was not performed on the adult cases during the period of this study.) All four patients presented acutely without a history of prior hematological disorder. In cases 1, 2, and 3, the diagnosis of ALL was made on the basis of morphology and cytochemical staining of cells from peripheral blood and marrow. In case 4, the initial diagnosis of lymphoblastic lymphoma was made on the histopathology of a lymph node biopsy. Leukemic marrow cells from cases 1, 2, and 3 were tested for receptors to a host of immunologic markers. All patients were treated with intensive combined chemotherapeutic protocols. All patients were given CNS prophylaxis that included intrathecal methotrexate and received from five to seven chemotherapeutic agents intermittently for maintenance therapy. Informed consent for all biopsy specimens was obtained.

Cytogenetic studies. Marrow cells were obtained from heparinized posterior iliac crest aspirates, and the specimens were processed within 30 minutes of aspiration. Both direct and 24-hour cultures were done in all cases, except case 3 in which the marrow was processed by direct methods only. Cells in cases 1, 2, and 4 were studied using routine cytogenetic techniques.[15] Case 3 was studied by the method of Williams et al.[16] G-banded metaphase chromosomes were obtained according to routine techniques.[17] In all cases, a minimum of 25 metaphases were examined.

RESULTS

Patients. Partial clinical data on all patients are included in Table 1. Complete remission was achieved in all patients. Case 4 relapsed after eight months and died. Case 2 relapsed after four months, was successfully reinduced, but died shortly thereafter. Cases 1 and 3 have both been in

complete and continuous hematologic remission for eight months.

Cytochemical and morphological findings. Leukemic marrow cells in all four cases showed typical L1 morphology[18] and negative staining with Sudan black. Cases 1, 2, and 4 showed positive staining with periodic acid-Schiff and with acid phosphatase, while in case 3, staining was negative with periodic acid-Schiff and acid phosphatase was not done. TdT expression was studied only in case 3 where it was found to be expressed in 60% of marrow cells. This value was not significantly different from that observed in other childhood cases of T cell ALL (median, 62%, n = 21) or in childhood cases of non-T cell ALL (median, 63%, n = 115). Sections of the lymph node from case 4 revealed a diffuse infiltration of neoplastic lymphoid cells with a high nuclear to cytoplasmic ratio, convoluted nuclei, indistinct nucleoli, and a fine chromatin pattern. These findings were compatible with a T cell lymphoma.

Immunologic markers. The immunologic markers that characterized the respective leukemic clones were as follows: case 1, T4$^+$, T10$^+$, T11$^+$, Leu 1$^+$, AET$^+$, CALLA$^-$, Ia$^-$, Ba-2$^-$; case 2, Leu 1$^+$, Leu 2$^+$, Leu 6$^+$, AET$^+$, SIg$^-$; and case 3, T4$^+$, T8$^+$, T11$^+$, Ba-1$^+$, AET$^+$, CALLA$^-$, Ia$^-$, Pan T$^+$, Pan B$^-$, SIg$^-$. These findings confirmed that the leukemic clones in these patients represented T lineage clonal expansions.

Cytogenetic studies. Cytogenetic analysis of leukemic marrow revealed the following karyotypes; case 1, 46,XY (1 cell)/46,XY,t(10;14)(q24;q11),del(22)(q13) (24 cells); case 2, 46,XY (9 cells)/46,XY,−4,−17,+mar,+der(4)t(4;17)(q31;q21),t(10;14)(q24;q11) (8 cells)/45,XY,−4,−4,−17,+der(4)t(4;17)(q31;q21),+der(4)t(4;17)(q31;q21),t(10;14)(q24;q11) (8 cells); case 3, 46,XY,t(10;14)(q24;q11); and case 4, 46,XY,t(10;14)(q24;q11). The consistent cytogenetic abnormality was t(10;14)(q24;q11). Partial karyotypes from cases 1, 3, and 4 are shown in Fig 1.

DISCUSSION

We have presented four cases of T cell leukemia/lymphoma that have in common the following translocation in the leukemic clone; t(10;14)(q24;q11). While translocations involving the proximal long arm of 14 and the long arm of 10 have been reported in T cell neoplasia, breakpoints in chromosome 10 were either not defined or assigned to a band other than 10q24;[19,20] (Of particular interest is a cell line with a t(10;14)(q23;11.2) established from a patient with T cell lymphoma in relapse.[20]) Our report is thus the first report of this translocation occurring as a nonrandom cytogenetic abnormality in any human cancer. The translocation was found in both the pediatric and adult age groups. Except for the T cell immunophenotype and marked leukocytosis, there were no other clinical or laboratory features in this series that correlated with the presence of the t(10;14).

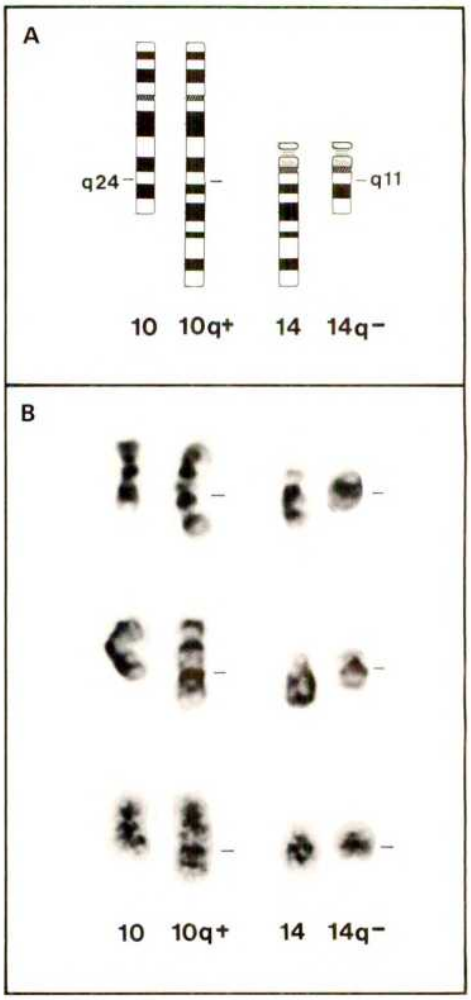

Fig 1. The 10;14 translocation associated with T cell neoplasia. (A) Diagram showing the G-banded pattern of rearranged chromosomes and homologues involved in the t(10;14)(q24;q11). (B) Representative partial karyotypes from three different patients with the t(10;14). Top, case 1; middle, case 4; and bottom, case 3. The lines indicate the approximate positions of the breakpoints.

The breakpoints observed in this translocation are intriguing. The one on chromosome 14 (q11) is in the region of the α-chain gene of the T cell antigen receptor[10] and is commonly[11,12] but not exclusively[21] involved in chromosomal rearrangements seen in T cell neoplasia. Based on the frequent observations in B cell neoplasia of translocations resulting in the juxtaposition, and subsequent deregulation, of the c-*myc* proto-oncogene with an immunoglobulin gene, it has been suggested that in T cell neoplasia, the T cell antigen receptor genes can assume the role played by the immunoglobulin genes in B cell neoplasia.[22] In support of this, Erikson et al have shown that the α-chain gene of the T cell receptor is split by a chromosomal translocation in two T cell leukemias.[23]

Several genes have been assigned to the distal long arm of chromosome 10,[24] including TdT.[14] The function of the TdT gene is not fully understood, but its expression is elevated in pre-B and pre-T cells.[25] It is also expressed at greatly elevated levels in lymphoblastic malignancies.[26] A common fragile site has been observed at 10q25,[13] and it has been suggested that fragile sites are predisposed to chromosomal mutation.[27] It is possible that the basis for the involvement of 10q24 in these four translocations lies simply in the generalized fragility of this region. It seems more likely, however, that a gene or genes important in T cell differentiation reside in 10q24. TdT may be such a gene and is a good candidate for playing a major role in T cell oncogenesis when its expression or coding sequence is altered as a result of juxtaposition to part or all of the α-chain gene of the T cell antigen receptor through aberrant recombination. Such an altered TdT that aberrantly or constitutively inserted nucleotides could be a potent carcinogen. Further studies are required to determine if TdT is different in cases of T cell neoplasia with the translocation compared to those without the t(10;14)(q24;q11).

ACKNOWLEDGMENT

The authors wish to thank Dr Mark Greenberg of the Division of Hematology/Oncology, The Hospital for Sick Children, Toronto, for referring case 1 for study; Dr Gary Dahl of the Department of Hematology/Oncology, St Jude Children's Research Hospital, Memphis, for referring case 3 for study; and Drs D. Reece and P. Klimo of the Cancer Control Agency of British Columbia for referring cases 2 and 4. The authors are also indebted to Sandra Johnson and Paul Gonsalves for providing expert technical assistance.

Cytogenetic studies were performed on cases 1 and 3 in the laboratories of Dr Ikuko Teshima of the Hospital for Sick Children, Toronto, and Dr Dorothy Williams of the St Jude Children's Research Hospital, Memphis, respectively.

CONCISE REPORT

Use of Oligonucleotide Hybridization in the Characterization of a β^0-Thalassemia Gene (β^{37} TGG→TGA) in a Saudi Arabian Family

By Corinne D. Boehm, Carol E. Dowling, Pamela G. Waber, Patricia J. V. Giardina, and Haig H. Kazazian, Jr

Analysis of restriction site polymorphisms in the β-globin gene cluster of a Saudi Arabian female with β^0-thalassemia demonstrated that both of her β-globin genes were missing a nonpolymorphic *Ava*II site in exon 2. Examination of the normal nucleotide sequence surrounding this *Ava*II site revealed that either of two nucleotide substitutions, TGG→TAG or TGG→TGA, could produce a nonsense codon at codon 37 and eliminate the *Ava*II site. Consequently, two oligonucleotides (19-mers spanning codons 36 through 41 and containing either TAG or TGA at codon 37) were synthesized and hybridized against genomic DNA of the proband and her family. Specific hybridization with one of the oligomers demonstrated that the patient's β^0-thalassemia was the result of homozygosity for the TGG→TGA mutation at codon 37. In certain cases, oligonucleotide hybridization using genomic DNA may obviate the need for gene cloning and sequencing in the characterization of point mutations.

© 1986 by Grune & Stratton, Inc.

THE USE OF synthetic oligonucleotide sequences for detection of single nucleotide differences in genomic DNA was pioneered by Wallace et al.[1,2] Oligomers have since been used for various diagnostic purposes, including prenatal detection of single-gene disorders such as α_1-antitrypsin deficiency,[3] sickle cell anemia and sickle hemoglobin C disease,[2,4] and certain β-thalassemias.[5-8] The discovery of a nonsense mutation in a factor VIII:C gene by use of oligonucleotide probes has recently been described.[9]

In the past decade, the molecular biology of the β^0- and β^+-thalassemias has been extensively studied. To date, 37 mutations have been described in peoples of Mediterranean, Middle Eastern, Asiatic Indian, and Pakistani, Chinese, Kurdish Jewish, and American black origin.[10-14] In general, each ethnic group has its own private set of β-thalassemia mutations, although exceptions, presumably due to more than one independent origin of the same mutation, have been observed.[10] To date, all point mutations producing β-thalassemia have been characterized by gene cloning and sequencing. Here we characterize a nonsense mutation in codon 37 of the β-globin gene by oligonucleotide hybridization.

MATERIALS AND METHODS

Subjects

The family studied is originally from Saudi Arabia. They deny any knowledge of consanguinity, although they are from the same village. They have hematologic values typical of β-thalassemia heterozygotes (mean corpuscular volume, mean corpuscular hemoglobin concentration, A_2 and hemoglobin values in the mother were 61.1fl, 31.3g/dl, and 7.8% and in the father were 65.4fl, 30.9g/dl, and 7%). The couple has two children with transfusion-dependent β^0-thalassemia and one child who is unaffected.

DNA Analysis

DNA was extracted by previously described methods from white blood cells of the mother, father, their daughter with β^0-thalassemia, and their homozygous normal daughter.[15] DNA was digested and Southern blots were prepared to examine β-globin region restriction site polymorphisms.[10,16] Haplotypes associated with the parental β^A- and β^{thal}-globin alleles were constructed through inheritance patterns observed in their affected and normal daughters.[17]

Oligonucleotide Analysis

Gel preparation and hybridization. After digestion, the DNA fragments were electrophoretically separated in a 1% agarose gel. Gels were prepared and hybridized with the end-labeled oligomers as previously described,[18] except that they were also prehybridized for 30 minutes at 37 °C in the hybridization buffer and then were hybridized with probe overnight at 55 °C (T_m minus 3 °C). Washes were as described,[18] except that a final two-minute wash in 2XSSPE at 56.5 °C (T_m minus 1.5 °C) was included. 1XSSPE is 10 mmol/L sodium phosphate pH 7.0, 0.18 mol/L NaCl, 1 mmol/L EDTA. The gel was first hybridized with oligomer B (Fig 1). After autoradiography, the gel-bound DNA was denatured, soaked in neutralization buffer, and rinsed in distilled water. The prehybridization and hybridization steps were repeated using oligomer A.

Probe preparation. Oligonucleotides were synthesized on an Applied Biosystems instrument. The full-length 19 nucleotide oligomer was further purified by electrophoresis through a 20% acrylamide gel of 1.5-mm thickness at 600 V for approximately six hours. After the 19-mer was excised from the gel, it was separated from acrylamide gel material by the crush-and-soak method.[18] Two hundred nanograms of each purified oligomer was incubated with 250 μCi of γ^{32}P-ATP (ICN No. 35020) and 3 to 5 units of T_4 polynucleotide kinase (New England Nuclear, No. NEE-101, Boston) at 37 °C for 40 minutes. The unlabeled oligomer was separated from the end-labeled product by polyacrylamide gel electrophoresis as described.[18] Typical specific activities were 3×10^8 cpm/μg of oligomer.

RESULTS

Polymorphism Haplotypes

To determine the feasibility of prenatal diagnosis for this couple, restriction site polymorphisms within and surrounding the β-globin gene were examined in the couple, one of their affected children, and a homozygous normal child. Haplotypes were determined using the following polymorphic restriction sites: *Hind*III within $^G\gamma$–, *Hind*III within $^A\gamma$–, *Hinc*II within $\psi\beta_1$–, *Hinc*II 3' to $\psi\beta_1$–, *Ava*II within $\psi\beta_1$–1, *Hinf*I 5' to β–, *Rsa*I 5' to β–, *Ava*II within β–, *Hind*III 3' to β–, and *Bam*HI 3' to β-globin genes. The

Ava II recognition sequence:	GG ACC
Normal β-globin sequence, codon 36-1st nucleotide of codon 42:	CCT TGG ACC CAG AGG TTC T
Oligomer A:	CCT **TGA** ACC CAG AGG TTC T
Oligomer B:	CCT **TAG** ACC CAG AGG TTC T

Fig 1. Normal sequence of a portion of exon 2 of the β-globin gene. Also shown are the sequences of two 19-mer oligonucleotide probes, each of which contains a nonsense codon at the position homologous to codon 37 of the β-globin gene. Both nonsense codons destroy the *Ava*II recognition site that is normally present.

β^{A}-globin–associated haplotypes in both parents were $- - - - + + +$ (β^{A}) $+ + +$. Both parental β^{thal}-globin–associated haplotypes were $- - - - + + -$ (β^{thal}) $+ + +$.

Mutation in an Ava*II Site*

When genomic DNA from this family was digested with *Ava*II and probed with β-cDNA sequences, a new band appeared at 3.2 kb, unaccompanied by the loss of any bands normally seen (Fig 2a). This new band was present in the DNA of both parents and their affected daughter. It was absent from the DNA of their homozygous normal daughter. The appearance of the 3.2-kb fragment is consistent with the loss of a nonpolymorphic *Ava*II site in exon 2 of the β–globin gene (Fig 2b). The newly created fragment would have sequence in common with the β-globin cDNA probe being used (JW 102), which extends from codon 20 to the 3′ untranslated portion of the gene.[19] On the other hand, when the *Ava*II site in intact, the fragment lying between this site and the next *Ava*II site in the 5′ direction is not detected by the β-cDNA probe because it has only about 50 bp of sequence in common with this probe.

Oligonucleotide Analysis

Two oligonucleotide probes were synthesized, each of which could detect one of the two nonsense mutations that, if present, would destroy the *Ava*II site (Fig 1). The probes were 19-mers and included the sequences of codons 36 through 41 and the first nucleotide of codon 42. After digestion of genomic DNA with *Bam*HI, the β-globin gene fragment that includes codons 35 through 41 is 1.9 kb. After hybridization of *Bam*HI-digested genomic DNA with oligomer B, there was no signal at 1.9 kb with any of the genomic DNAs tested (Fig 3). This result indicated that TGG → TAG at codon 37 was not the mutation responsible for β°-thalassemia in this family. Subsequent hybridization of the same gel with oligomer A, which contained the nonsense codon TGA at the same position, revealed a 1.9-kb hybridizing fragment in the father, mother, and their affected daughter but not in their homozygous normal daughter nor in any of the control samples (Fig 3).

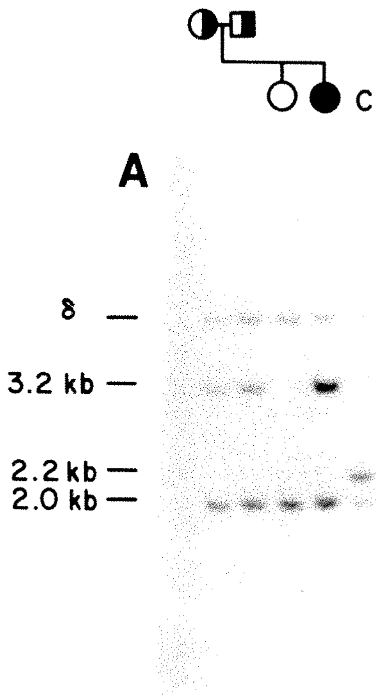

Fig 2. (A) Autoradiogram of *Ava*II-digested genomic DNA from family members indicated by the pedigree. β-Globin cDNA (JW 102) was used as the probe. The two alleles of an *Ava*II polymorphism in IVS 2 of the gene appear as 2.2-kb and 2.0-kb fragments on the autoradiogram. All family members are homozygous for the presence of the polymorphic site (+/+), and the control (c) is heterozygous +/−. A new band at 3.2 kb is seen in this family and is segregating with the β-thalassemia allele. The appearance of this fragment indicates loss of a nonpolymorphic *Ava*II site in exon 2 of the β-globin gene. Probe cross hybridizes with δ-globin sequences. (B) *Ava*-II restriction map of a normal β-globin gene and the mutant β-globin gene described in the text. Solid arrows (↑) indicate the locations of the nonpolymorphic *Ava*II restriction sites within and flanking the β-globin gene. Solid arrows with asterik (↑*) indicate the location of a polymorphic *Ava*II site, which is present in both the mutant and normal β-globin genes. Open arrow (↑) indicates the location of the nonpolymorphic *Ava*II site, which is destroyed in the mutant gene. The 3.0-kb fragment is not seen in the autoradiogram in Fig 2a because the 5′ end of the JW 102 β-globin cDNA probe is complementary to only about 50 bp of this fragment.

DISCUSSION

Coding region mutations producing β-thalassemia are of several types, including frameshift mutations due to small deletions or insertions, mutations that affect cryptic splice sites, or chain terminator (nonsense) mutations.[10] Any of these can cause loss of an endonuclease restriction site.[20-23] In addition, clinically insignificant, or neutral, nucleotide substitutions within coding regions can also eliminate an endonuclease restriction site.[24,25] In the case described here, DNA restriction analysis indicated that a nonpolymorphic *Ava*II site in exon 2 of the β-globin gene was absent in a β°-thalassemia allele. Both codons 37 and 38 are part of the *Ava*II recognition sequence (GGACC) that is lost in this β°-thalassemia allele (Fig 1). An insignificant substitution in the third nucleotide of codon 38 (ACC → ACT, ACA, or ACG) could be responsible for the loss of the *Ava*II site and be unrelated to the mutation producing β°-thalassemia. In contrast, a frameshift mutation due to insertion or deletion of nucleotides in codon 37 or 38 or both could eliminate the

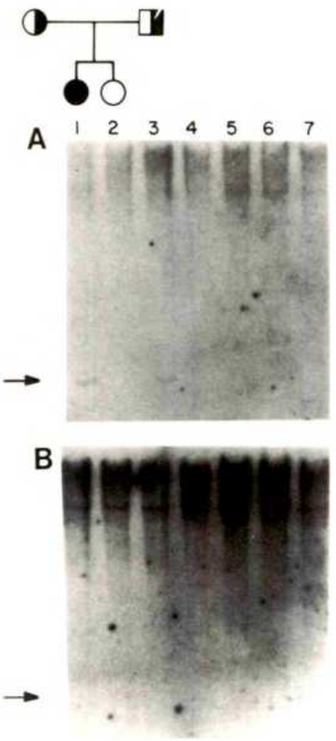

Fig 3. **Autoradiograms of *Bam*HI-digested genomic DNA from family members shown in the pedigree. The gel was hybridized initially with oligomer B (panel B), which contains the TAG nonsense codon, and then subsequently hybridized with oligomer A (panel A), which contains the TGA nonsense codon (see Materials and Methods). Arrows in panels A and B indicate the location of the 1.9-kb *Bam*HI fragment in which codon 37 resides. Lanes are (1) β^0-thalassemia patient described here, (2) her β^A/β^A sister, (3) her β^A/β^{thal} father, and individuals (4) homozygous for nonsense codon 39 mutation, (5) heterozygous for nonsense codon 39 mutation, and (6) and (7) homozygous for normal β-globin alleles. Hybridization with DNA of the β^A/β^{thal} mother was readily visible with oligomer A but was too weak to be seen in the reproduction, and that lane has been omitted from the figure.**

*Ava*II site and produce β^0-thalassemia. Such a mutation would be difficult to characterize without cloning and sequencing the affected gene. However, the *Ava*II site could also be lost by either of two single nucleotide changes, producing nonsense mutations in codon 37 (TGG to either TAG or TGA). Oligonucleotide hybridization was chosen as a method with which we could determine relatively easily whether or not one of these nonsense mutations was present. Oligomer A identified the presence of a single nucleotide change G → A in codon 37, producing a TGA nonsense mutation.

This nonsense 37 mutation has not been observed among 400 or so Mediterranean, Indian, and Oriental β-thalassemia genes that we have examined by *Ava*II analysis with the JW102 β-globin probe. The molecular basis of β-thalassemia in Saudi Arabians, however, has not been extensively studied. Thus the frequency of the nonsense 37 allele in this population is not known. Although consanguinity is not known to be the case in this family, it may be the reason for the homozygous presentation of this allele.

The polymorphism haplotype associated with the nonsense 37 mutation is a subset of the haplotype I described in Orkin et al[24] and is a haplotype commonly associated with β^A-globin alleles. The parental β^A-associated haplotypes are identical with one another and differ from the nonsense 37-associated haplotype only at the *Rsa*I site 5′ to the β-globin gene.

NOTE ADDED IN PROOF

The gel used in Fig 3 was subsequently hybridized with an oligonucleotide probe corresponding to normal sequence at codons 36 through 41. DNA from the affected girl did not hybridize to this oligonucleotide probe, while that of other family members demonstrated a band at 1.9 kb. This indicates that the patient is homozygous for the β^{37} mutation.

CONCISE REPORT

The Cofactor Role of Protein S in the Acceleration of Whole Blood Clot Lysis by Activated Protein C In Vitro

By Nanneke J. de Fouw,*† Frits Haverkate,* Rogier M. Bertina,† Jaap Koopman,* Aat van Wijngaarden,†
and Victor W.M. van Hinsbergh*

The effect of purified human activated protein C (APC) and protein S on fibrinolysis was studied by using an in vitro blood clot lysis technique. Blood clots were formed from citrated blood (supplemented with ^{125}I-fibrinogen) by adding thrombin and Ca^{2+}-ions; lysis of the clots was achieved by adding tissue-type plasminogen activator. The release of labeled fibrin degradation products from the clots into the supernatant was followed in time. We clearly demonstrated that APC accelerates whole blood clot lysis in vitro. The effect of APC was completely quenched by anti-protein C IgG, pretreatment of APC with diisopropylfluorophosphate, and preincubation of the blood with anti-protein S IgG. This demonstrates that both the active site of APC and the presence of the cofactor, protein S, are essential for the expression of the profibrinolytic properties. At present, the substrate of APC involved in the regulation of fibrinolysis is not yet known. Analysis of the radiolabeled fibrin degradation products demonstrated that APC had no effect on the fibrin cross-linking capacity of factor XIII.

© 1986 by Grune & Stratton, Inc.

PROTEIN C is a vitamin K-dependent plasma protein that, on activation by thrombin/thrombomodulin, exerts anticoagulant activity by inactivating coagulation factors Va and VIIIa.[1,2] Protein S, another vitamin K-dependent plasma protein,[3] serves as a cofactor for activated protein C (APC) in expressing this anticoagulant effect.[4,5]

Several investigators presented evidence that APC is not only a potent anticoagulant, but also has profibrinolytic properties (both in vitro and in vivo).[6-9] Comp and Esmon[6] reported increased plasma plasminogen activator activity after infusion of bovine APC into dogs, which they considered to be a result of stimulation of tissue-type plasminogen activator (t-PA) release from the vessel wall by a secondary messenger triggered by APC. However, Colucci et al[7] could not establish any increase of fibrinolytic activity in squirrel monkeys, neither after administration of human APC nor thrombin–thrombomodulin complex. In vitro, Taylor et al[8] reported that APC enhances blood clot lysis.

So far no experimental data have been presented on whether protein S serves as a cofactor for APC in its profibrinolytic effects. In the present study, we investigated a possible role of human APC and protein S in t-PA–dependent fibrinolysis in vitro by means of a whole blood clot lysis method. Complete lysis of the whole blood clot was achieved within three hours by the addition of purified human t-PA. The results clearly demonstrate that APC enhances blood clot lysis in vitro and that protein S is an essential cofactor for this effect of APC. A preliminary report of these studies has been presented the Tenth International Congress on Thrombosis and Haemostasis, San Diego.[9]

MATERIALS AND METHODS

Whole blood clot lysis. Blood from healthy donors was collected by venipuncture in plastic tubes in 1/10 vol of 0.11 mol/L sodium citrate and supplemented with 7.5 μL of ^{125}I-labeled fibrinogen solution per milliliter, 30 or 60 IU t-PA/mL, APC (final concentration 7.75, 15.5, 46.5 nmol/L), and a vol of 0.15 mol/L NaCl to obtain a final blood concentration of 80%. After rapid mixing, 250 μL aliquots were transferred to Eppendorf cups containing 3 μL of 60 μmol/L thrombin solution and 2.5 μL of 1.25 mol/L CaCl$_2$. Immediately after mixing, the cups were incubated at 37 °C to allow clot formation and subsequent lysis. Clot formation occurred within 60 seconds. At that time, 90% of the ^{125}I-fibrinogen was incorporated into the clot. At different time intervals, tubes were centrifuged in a MSE Micro Centaur centrifuge (Beun de Ronde, Amsterdam) for five minutes 11.50 g (4 °C). The supernatant (100 μL) was mixed with 100 μL of a solution containing 2% sodium dodecyl sulfate (SDS), 20% glycerol, 6 mol/L urea, and 0.1 mol/L Tris/HCl buffer, pH 6.8, counted for radioactivity (^{125}FDP[fibrin degradation products] in a gamma counter (Packard 5110P, BC Netherlands) and analyzed by SDS-polyacrylamide gel electrophoresis, according to Laemmli.[10] Clot lysis was expressed as x-b/t-b × 100%, in which x = radioactivity of the supernatant, b = radioactivity of the blanc, t = total radioactivity added before clotting. The blanc value (<10%) is the radioactivity of the supernatant of whole blood 30 minutes after clotting and without addition of t-PA. One hundred percent lysis indicates complete clot lysis. After electrophoresis, autoradiography of the slab gels was carried out with a Kodak-X-ray Omat AR film (Kodak X-omatic regular) for 72 hours. Quantitatively similar results were obtained with blood of different donors at both t-PA concentrations.

Fibrinogen (Fbg) was isolated from human plasma, as described previously,[11] and labeled with ^{125}I by the iodogen method.[12] The molar ratio Fbg/iodine was approximately 2. The amount of radioactivity not clottable with thrombin was less than 10% of the total radioactivity. The radiolabeled Fbg, dissolved in 0.15 mol/L NaCl, had a concentration of 2 mg/mL and a specific radioactivity of 75.10^6 cpm/mg.

Human alpha (α) thrombin was prepared and purified as described previously.[13]

The two-chain form of t-PA was isolated from human (Bowes) melanoma cells and purified as described.[14] This activator is considered to be identical with the plasminogen activator in blood after its release from the vessel wall.[15]

Protein C was purified and activated as described previously.[13,16] Fibrinolytic activity could not be detected in the APC preparation, neither on plasminogen-rich fibrin plates[17] nor in a t-PA assay with the chromogenic substrate S-2251 (Kabi Vitrum, Stockholm).[18] APC was inactivated with diisopropylfluorophosphate (DFP) or with anti-protein C IgG as described previously.[19] One milliliter of anti-protein C IgG (2 mg/mL) completely neutralizes the protein C activity of 25 mL of pooled normal plasma within 15 minutes.

Neutralization of blood protein S with antiprotein S IgG. Blood was incubated for 15 minutes at 37 °C with antiprotein S IgG (100 μg/mL) prepared from rabbit antiserum against purified human protein S.[20] Under these experimental conditions, 1 mL of anti-protein S IgG (2.0 mg/mL) neutralizes the APC-cofactor activity of the protein S of 10 mL of pooled normal plasma completely. Antiprotein S IgG did not influence the APC activity as was measured by an amidolytic assay using S-2366.

RESULTS

Figure 1 shows that APC, added to the blood before clot formation was induced by thrombin and Ca^{2+}, greatly accelerates the lysis rate of the clot and that the effect increases with higher APC concentrations. Similar results were obtained with blood that had not been anticoagulated with citrate (data not shown). Because the lysis of blood clots from different donors showed different lysis rates at the same concentrations t-PA, the effect of APC was studied routinely at two t-PA concentrations (30 and 60 IU/mL). At both concentrations, APC had an accelerating effect on clot lysis. APC pretreated with anti-protein C-IgG or inactivated by DFP (Fig 2) no longer accelerated the lysis of blood clots. To neutralize all endogenous protein C, blood was preincubated with anti-protein C IgG, clotted, and lysed as described. A small inhibitory effect on the lysis rate was observed compared with normal blood (Fig 3). This indicates that part of the endogenous protein C, when activated by thrombin to APC, might contribute to the rate of clot lysis in vitro.

To investigate whether protein S plays a role in the acceleration of clot lysis by APC, blood protein S was neutralized before clotting with antiprotein S IgG. The effect of APC on clot lysis was completely quenched when all protein S was inactivated (Fig 4). Incubation of blood with nonimmune rabbit IgG had no effect on clot lysis either in the absence or presence of APC (not shown). To study whether APC has any effect on the cross-linking capacity of factor XIII, and therefore accelerates clot lysis,[21] the radioactive FDP formed in the supernatants were separated on SDS-polyacrylamide gels and visualized by autoradiography. A D-dimer band and degradation products with a higher molecular weight than fibrin (340 kd) were identified as cross-linked FDP. No differences in electrophoresis patterns of FDP from clots lysed with and without APC present were found when compared on the basis of an equal percentage of lysis. This indicates that the extent of cross-linking by factor XIII was not influenced by APC (data not shown).

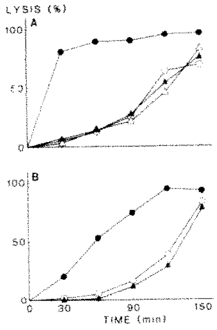

Fig 2. Effect of APC inactivated by pretreatment with anti-protein C IgG (A) and with DFP (B) on the lysis rate of blood clots. Citrated whole blood from healthy donors (A: A.v.W.; B: F.H.) was clotted and lysed as described in Materials and Methods. Thirty International Units t-PA per milliliter of blood was used. Curves represent lysis without addition of APC (○), after addition of 46.5 nmol/L APC (●), 46.5 nmol/L APC pretreated with antiprotein C IgG (△), 75 μg anti-protein C IgG/mL blood (▲, A), and of 16 nmol/L APC pretreated with DFP (▲, B).

DISCUSSION

In the present study, we demonstrated by means of a t-PA-dependent whole blood clot lysis method that human APC added before clotting greatly accelerates the lysis rate of whole human blood clots in vitro. Active APC is required for this effect, since APC inactivated with antiprotein C IgG or DFP did not show an accelerating effect on clot lysis. Several other investigators have suggested a possible role for APC in fibrinolysis.[6-9,19,22,23] An acceleration of blood clot lysis in vitro has been previously reported by Taylor et al.[8] In their experiments, complete lysis was achieved during incubation periods up to 30 hours. This may not be an optimal

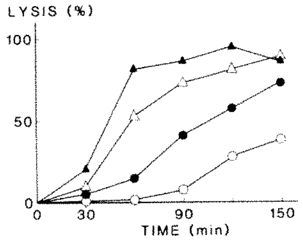

Fig 1. Influence of APC on the lysis of human blood clots in vitro. Citrated whole blood from a healthy donor (P.K.) was clotted and lysed as described in Materials and Methods. Thirty International Units t-PA per milliliter of blood was used. Curves represent lysis without addition (○) and with 7.75 nmol/L (●), 15.5 nmol/ (△), 46.5 nmol/L (▲) APC.

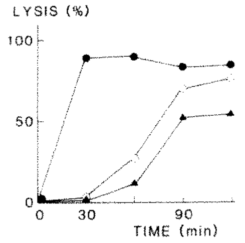

Fig 3. Contribution of endogenous APC to the acceleration of blood clot lysis. Citrated whole blood from a healthy donor (A.v.W.) was incubated for 15 minutes at 37 °C with antiprotein C IgG (75 μg/mL) (▲) or saline (○, ●) clotted and lysed as described in Materials and Methods. Sixty International Units per milliliter t-PA was used. Curves represent lysis without addition of exogenous APC (○, ▲) or after addition of 46.5 nmol/L APC (●).

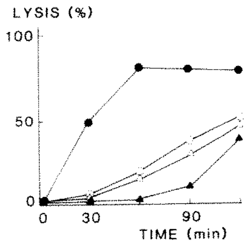

Fig 4. Effect of the elimination of protein S on the APC-induced acceleration of whole blood clot lysis. Citrated whole blood from a healthy donor (F.H.) was incubated for 15 minutes at 37 °C with antiprotein S IgG (100 μg/mL) (triangles) or saline (circles) clotted and lysed as described in Materials and Methods. Sixty International Units t-PA was used. Curves represent lysis without addition of APC (○, ▲) and after the addition of 46.5 nmol/L APC (●, △).

condition for correlation changes in lysis rate with APC concentrations, since the half-life of APC in blood is about 20 minutes, due to the presence of a protein C inhibitor.[24]

So far no data have been published on the role of protein S in fibrinolysis. From previous studies, it is known that the prolongation of the activated partial thromboplastin time by APC is dependent on the presence of protein S, and that the inactivation of factor Va by APC depends on the presence of phospholipids and Ca^{2+} ions and is greatly accelerated by the addition of protein S.[25] Walker[5] proposed that protein S increases the affinity of APC for binding to phospholipid membranes, and thus accelerates the proteolytic degradation of factor Va on the phospholipid surface. In this report (Fig 4), we demonstrate that protein S is an obligatory cofactor of APC for its accelerating effect on in vitro fibrinolysis. This observation also suggests that procoagulant phospholipids, which become available by platelet activation, might be involved in the action of APC on the fibrinolytic system.

At present, no definitive information is available on the mechanism by which APC accelerates t-PA–dependent fibrinolysis. Because no differences were found in electrophoresis patterns of FDP from clots lysed with and without APC present, it seems unlikely that APC interferes with the cross-linking capacity of factor XIII. Another possible mechanism might be that APC inactivates an inhibitor of t-PA, and thus increases the concentration of active t-PA. Indeed, we and others found that APC decreases plasminogen activator activity in endothelial cell-conditioned medium.[19,22] However, the complexity of the clot lysis system does not permit us to extrapolate our data to those obtained in the t-PA inhibitor experiments in endothelial cell culture systems. Taylor and Lockhart[23] suggested that APC inhibited a plasminogen activator inhibitor released by phorbol diester-stimulated mononuclear cells, thus inducing acceleration of fibrinolysis.

LEFT SHIFT OF PERIPHERAL BLOOD COUNT AT DIAGNOSIS OF CHILDHOOD ACUTE LYMPHOBLASTIC LEUKEMIA

To the Editor:

The presence of myeloid precursors in the blood (left shift) is a well-recognized presenting feature in some cases of childhood acute lymphoblastic leukemia (ALL).[1] Shen et al,[2] in a retrospective analysis of 109 children with ALL, found that left shift (in 43% of the patients) was correlated with longer durations of complete remission. The authors postulated that this feature may be an indirect measure of total leukemia cell burden, reflecting less suppression of granulopoiesis. Otherwise, very little is known about the clinical importance of left shift in the peripheral blood.

Between May 1979 to December 1983, 427 children with newly diagnosed ALL were admitted to St Jude Children's Research Hospital. They were subjects of a Total Therapy study that incorporated three different treatment protocols based on the patients' initial risk features and subsequent randomization. The details of risk assignment and treatment have been previously published.[3] Seventy-four patients (17.3%) were found to have a left shift in their blood counts, defined by the presence of 1% or more of metamyelocytes, myelocytes, or promyelocytes in a differential count of 100 cells. Children with left shift were also more likely to have circulating nucleated red blood cells (20 of 74 patients versus 35 of 353, $P < 0.001$). By comparison with common ALL, cases of T cell and so-called "undifferentiated" ALL had higher frequencies of left shift: 44 of 304 (14%), 15 of 59 (25%), and 8 of 26 (31%), respectively ($P = 0.02$). The presence or absence of left shift was not related to age, sex, race, French-American-British (FAB) morphologic subtype, percentage of S-phase cells, blast cell DNA index, liver or spleen size, initial leukocyte count, percentage of blasts in bone marrow, platelet count, hemoglobin level, or serum lactic dehydrogenase level. More importantly, with a median follow-up time of 4 years 2 months, left shift had no impact on treatment outcome whether the analysis was performed on combined (Fig 1) or separate protocol groups.

The reason for the lower percentage of patients with left shift in our series compared with that of Shen et al[2] is not clear. Nonetheless, we were unable to demonstrate any association between left shift and leukemia cell burden as reflected by leukocyte count, liver or spleen size, percentage of blasts in bone marrow, and serum lactic dehydrogenase level.[4] The similarity of relapse-free survival times for patients with or without left shift in our study contrasts with the results of Shen et al.[2] These findings indicate that left shift is a relatively unimportant presenting feature and support the idea that prognostic factors in childhood ALL can differ with changes in therapy.[5,6]

To the Editor:

There are two major differences between the findings of Pui et al and our own. The first and obvious one is that left shift (LS) in their series is not a prognostic indicator. The second is the presence of LS in 47/109 of our patients, but only 74/427 of their patients. Clearly, then, the patient subpopulation defined as having LS is markedly different in the two studies. There are a number of ways in which this may have arisen. Morphologic interpretation was subjective, and was done by light microscopy in our series. We do not know how it was done in the St Jude study. Perhaps the differential counts were performed on automated equipment. Our patient referral pattern is different from the St Jude one. We are an urban center, not a national referring institution. Perhaps our patients are admitted

Blood, Vol 67, No 4 (April), 1986: pp 1193-1194

earlier than in St Jude's, and their leukemic cell load may be less. In our recent leukemia study, 182/230 patients presented with a white cell count at diagnosis of $< 30 \times 10^9/L$ and 115 had a white cell count of $< 10 \times 10^9/L$. There are, of course, other possibilities such as sample size differences, or the different intensity of chemotherapy treatment eliminating the prognostic value of LS.

Our findings on the prognostic value of LS led us to undertake in vitro studies on the effect of bone marrow leukemia cell underlayers on the growth of normal bone marrow in the presence and absence of leukocyte conditioned media (LCM) in microcell agar culture. We found growth of normal marrow and leukemia underlayers without LCM in 7/12 underlayers prepared from patients with LS, but in only two out of eight prepared from underlayers of patients with ALL and no LS ($P = 0.09$). There is therefore some in vitro experimental evidence that the interaction between leukemia blasts and normal stem cells may be very complicated and variable, and that LS in the peripheral blood may be an indirect indicator of this balance.

ANNOUNCEMENTS

PETER DEBYE-PRIZE 1987 IN CARDIOVASCULAR DISEASES

The University of Limburg at Maastricht, The Netherlands, has been given the opportunity to award the Peter Debye-prize. This prize, in the amount of 20,000 guilders, is an award of appreciation. The funds for the Peter Debye-prize are provided by the Edmond Hustinx Foundation, founded by the Maastricht industrialist Edmond Hustinx, who was greatly interested in promoting science and culture. The prize is named after the physicist Peter J.W. Debye (1884–1966), a native of Maastricht, who was awarded the Nobel Prize for chemistry in 1936.

In January 1987 the prize will be presented for the fifth time, to a person or group of persons (three persons maximum) considered to have made a fundamental contribution to research in the field of cardiovascular diseases, particularly in molecular-chemical aspects, including arteriosclerotic processes, blood coagulation, ischemia, reperfusion, and chemical kinetics of substrates, ions, and macromolecules in the heart.

An international jury has been formed for the awarding of this prize. This jury would like its attention drawn to persons or groups of persons from any country to be considered for the award on the basis of their scientific work in the area indicated.

Nominations (in English) should include a curriculum vitae, a survey of the scientific achievements of the candidate(s) (not exceeding four pages), and a list of publications. The deadline for nominations is September 1, 1986. Further information about the prize is available from Dr. E.H.S. Drenthe, Secretary of the Jury, Office of the Rector, University of Limberg, PO Box 616, 6200 MD Maastricht, The Netherlands.

EXECUTIVE DIRECTOR

An Executive Director is being sought for the Puget Sound Blood Center in Seattle, Washington. The PSBC is a centralized regional blood banking facility that employs 240 people, including seven physicians, and is responsible for the distribution of 250,000 units of blood components annually. Candidates must have an MD degree and have demonstrated administrative skills in transfusion medicine and the ability to contribute to and broaden the ongoing research activities of the Center. The position carries a senior faculty appointment in the School of Medicine at the University of Washington. Interested candidates should send their CV and bibliography as well as the names of three references to Dr. Daniel H. Coleman, c/o Search Committee, Puget Sound Blood Center, Terry and Madison Streets, Seattle, Washington 98104. The PSBC is an Equal Opportunity Employer.

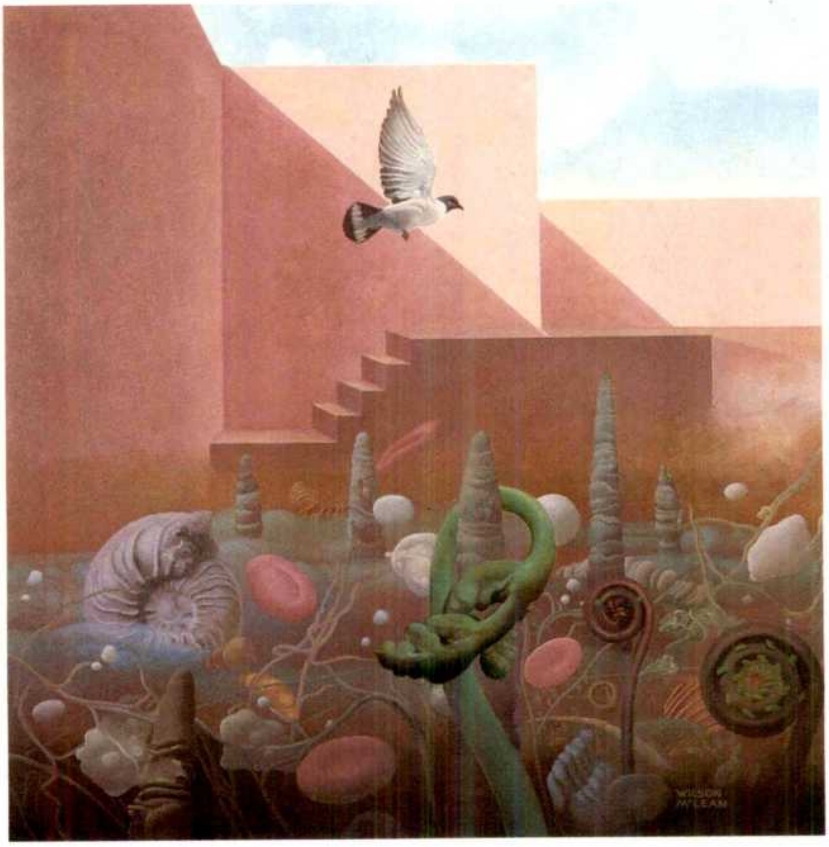
ADVANCES IN HAEMATOLOGY

Monday, June 9, to Friday, June 13, 1986
Hammersmith Hospital and the Royal Postgraduate Medical School, London

The course will cover selected topics in scientific foundation and clinical aspects of haematology. A detailed program will be available to applicants. Certified for Continuing Medical Education credit in the USA. Cost (including catering) $300 US.

Direct inquiries to Mrs E. Barker, School Office, Royal Postgraduate Medical School, Du Cane Road, London W12 OHS, England. Telephone: 01-740 3117/3118.

NOW THE WAY IS CLEAR FOR YOU TO PROVIDE LEUKOPOOR PLATELETS

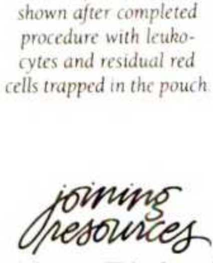


...WITH THE CUTTER LEUKOTRAP™ PLATELET POOLING SYSTEM.

Now, leukopoor platelets can be routinely used for treatment of patients on platelet therapy to reduce or eliminate leukocyte-associated transfusion reactions. Leukotrap is the first commercially available system for *routine* production of leukopoor platelets.

MOST EFFICIENT METHOD

The Leukotrap System removes 90% of leukocytes and residual red cells with only 10% platelet loss.



Leukotrap™ Pooling Bag shown after completed procedure with leukocytes and residual red cells trapped in the pouch.

SIMPLE, FAST PROCEDURE

The Leukotrap System requires minimal technician time and a standard centrifuge.

Provide a better platelet product...with the Leukotrap Platelet Pooling System.

TECHNICON H•1 SYSTEM THE INFLUENCE GROWS

It's no wonder that TECHNICON'S sphere of influence in hematology is growing rapidly. All it took was the new TECHNICON H•1™ system. This hematology analyzer is already providing a growing list of labs with a CBC, platelets, a FULL white cell differential, and RBC morphology plus lymphocyte subset analysis. All from one sample, at one work station, in one minute and on one comprehensive report form. As the TECHNICON H•1 systems are delivered, the influence grows. Let us influence you. For more information write: Ms. Lou Ann Page, TECHNICON INSTRUMENTS CORP., 511 Benedict Ave., Tarrytown, NY 10591.

HERPES SIMPLEX INFECTION IN THE COMPROMISED HOST:

OFTEN SERIOUS, TOO OFTEN UNSUSPECTED

Number one in a series of typical case presentations.

Esophagitis in a leukemia patient

In patients with hematologic malignancies, the visceral organ most frequently involved by herpes simplex virus (HSV) infection is the esophagus.[1] Extensive ulcerative lesions may develop on the upper two thirds of the esophagus with confluent lesions of the distal third.[2] In some cases, however, the mucosa may be grossly unremarkable even when microscopic examination shows evidence of herpetic ulcerative esophagitis.[1] Similarly, some patients may display symptoms of dysphagia and burning retrosternal pain,[3] whereas others may appear asymptomatic.[1] The diagnostic method of choice for patients with suspected herpetic esophagitis is esophagoscopy with visualization of the mucosa and procurement of cytologic and biopsy specimens from ulcerated areas.[1]

Herpetic infections may result in extensive disease and death

Immunocompromised patients are highly vulnerable to HSV infection. Such infections may interrupt therapy and even lead to death if not detected early and managed aggressively.[1] Although the initial appearance may be mild, HSV infection may progress to severe localized mucocutaneous ulcerations. The greatest threat that herpes simplex poses is an infection that disseminates from a mucocutaneous or unrecognized primary lesion and involves the lungs, liver, esophagus, or central nervous system.[1] Furthermore, herpetic ulcers frequently provide an entry for secondary bacterial and fungal pathogens.[2]

Infections may not be diagnosed correctly without virologic study

Some investigators claim that the actual incidence of serious HSV infection is probably higher than reported because "the possibility of herpetic disease is insufficiently considered and appropriate diagnostic viral studies are often not carried out."[3] One study, for example, found histocytologic evidence of visceral herpes infection in 56 patients even though herpetic involvement was not suspected in any of the patients prior to autopsy.[2]

ZOVIRAX I.V. halts viral replication and speeds healing even in debilitated patients

ZOVIRAX I.V. has been shown to be a highly effective treatment for severe mucocutaneous HSV infection in immunocompromised patients. In controlled trials, ZOVIRAX I.V. rapidly halted viral shedding — within 3 days in most patients — and significantly shortened healing time as well as duration of pain.[4,5] Furthermore, ZOVIRAX I.V. may allow patients to return home sooner and enable patients with intraoral lesions to resume normal eating habits.[6]

ZOVIRAX I.V. is well tolerated by immunocompromised patients

A multicenter collaborative trial of ZOVIRAX I.V. in immunocompromised patients reported that: "Clinical benefits were obtained without appreciable toxicity. The most common reactions were irritation of peripheral veins used for drug infusion and a low incidence of rash.... Significant renal or hematologic toxicity did not occur, even in these seriously ill patients who were commonly receiving other drugs concomitantly."[5]

Note: Approximately 1% of patients receiving intravenous acyclovir have manifested encephalopathic changes. Please see brief summary for more information.

An effective response to a life-threatening infection
ZOVIRAX® I.V. INFUSION
(acyclovir sodium) sterile powder

An effective response to a life-threatening infection

ZOVIRAX® I.V. INFUSION

(acyclovir sodium) sterile powder

FOR INTRAVENOUS INFUSION ONLY

INDICATIONS AND USAGE: Zovirax Sterile Powder is indicated for the treatment of initial and recurrent mucosal and cutaneous Herpes simplex (HSV-1 and HSV-2) infections in immunocompromised adults and children. It is also indicated for severe initial clinical episodes of herpes genitalis in patients who are not immunocompromised.

These indications are based on the results of several double-blind, placebo-controlled studies which evaluated the drug's effect on virus excretion, complete healing of lesions, and relief of pain.

Herpes Simplex Infections in Immunocompromised Patients

A multicenter trial of Zovirax Sterile Powder at a dose of 250 mg/M^2 every 8 hours (750 mg/M^2/day) for 7 days was conducted in 97 immunocompromised patients with oro-facial, esophageal, genital and other localized infections (50 treated with Zovirax and 47 with placebo). Zovirax significantly decreased virus excretion, reduced pain, and promoted scabbing and rapid healing of lesions.[1,2,3]

Initial Episodes of Herpes Genitalis

A controlled trial was conducted in 28 patients with severe initial episodes of herpes genitalis with a Zovirax dosage of 5 mg/kg every 8 hours for 5 days (12 patients treated with Zovirax and 16 with placebo). Significant treatment effects were seen in elimination of virus from lesions and in reduction of healing times.[4]

In a similar study, 15 patients with initial episodes of genital herpes were treated with Zovirax 5 mg/kg every 8 hours for 5 days and 15 with placebo. Zovirax decreased the duration of viral excretion, new lesion formation, duration of vesicles and promoted more rapid healing of all lesions.[5]

Diagnosis

The use of appropriate laboratory diagnostic procedures will help to establish the etiologic diagnosis. Positive cultures for Herpes simplex virus offer a reliable means for confirmation of the diagnosis. In initial episodes of genital herpes, appropriate examinations should be performed to rule out other sexually transmitted diseases. Whereas cutaneous lesions associated with Herpes simplex infections are often characteristic, the finding of multinucleated giant cells in smears prepared from lesion exudate or scrapings may assist in the diagnosis.[6]

CONTRAINDICATIONS: Zovirax Sterile Powder is contraindicated for patients who develop hypersensitivity to the drug.

WARNINGS: Zovirax Sterile Powder is intended for intravenous infusion only, and should not be administered topically, intramuscularly, orally, subcutaneously, or in the eye. Intravenous infusions must be given over a period of at least 1 (one) hour to prevent renal tubular damage (see PRECAUTIONS and DOSAGE AND ADMINISTRATION).

PRECAUTIONS:

General: The recommended dosage, frequency and length of treatment should not be exceeded (See DOSAGE AND ADMINISTRATION).

Although the aqueous solubility of acyclovir sodium (for infusion) is >100 mg/ml, precipitation of acyclovir crystals in renal tubules can occur if the maximum solubility of free acyclovir (2.5 mg/ml at 37°C in water) is exceeded or if the drug is administered by bolus injection. This complication causes a rise in serum creatinine and blood urea nitrogen (BUN), and a decrease in renal creatinine clearance. Ensuing renal tubular damage can produce acute renal failure.

Abnormal renal function (decreased creatinine clearance) can occur as a result of acyclovir administration and depends on the state of the patient's hydration, other treatments, and the rate of drug administration. Bolus administration of the drug leads to a 10% incidence of renal dysfunction, while in controlled studies, infusion of 5 mg/kg (250 mg/M^2) over an hour was associated with a lower frequency — 4.6%. Concomitant use of other nephrotoxic drugs, pre-existing renal disease, and dehydration make further renal impairment with acyclovir more likely. In most instances, alterations of renal function were transient and resolved spontaneously or with improvement of water and electrolyte balance, drug dosage adjustment or discontinuation of drug administration. However, in some instances, these changes may progress to acute renal failure.

Administration of Zovirax by intravenous infusion must be accompanied by adequate hydration. Since maximum urine concentration occurs within the first 2 hours following infusion, particular attention should be given to establishing sufficient urine flow during that period in order to prevent precipitation in renal tubules.

When dosage adjustments are required they should be based on estimated creatinine clearance (See DOSAGE AND ADMINISTRATION).

Approximately 1% of patients receiving intravenous acyclovir have manifested encephalopathic changes characterized by either lethargy, obtundation, tremors, confusion, hallucinations, agitation, seizures or coma. Zovirax should be used with caution in those patients who have underlying neurologic abnormalities and those with serious renal, hepatic, or electrolyte abnormalities or significant hypoxia. It should also be used with caution in patients who have manifested prior neurologic reactions to cytotoxic drugs or those receiving concomitant intrathecal methotrexate or interferon.

Exposure of HSV isolates to acyclovir *in vitro* can lead to the emergence of less sensitive viruses. These viruses usually are deficient in thymidine kinase (required for acyclovir activation) and are less pathogenic in animals. Similar isolates have been observed in 6 severely immunocompromised patients during the course of controlled and uncontrolled studies of intravenously administered Zovirax. These occurred in patients with congenital severe combined immunodeficiencies or following bone marrow transplantation. The presence of these viruses was not associated with a worsening of clinical illness and, in some instances, the virus disappeared spontaneously. The possibility of the appearance of less sensitive viruses must be borne in mind when treating such patients. The relationship between the *in vitro* sensitivity of herpesviruses to acyclovir and clinical response to therapy has yet to be established.

Drug Interactions: Co-administration of probenecid with acyclovir has been shown to increase the mean half-life and the area under the concentration-time curve. Urinary excretion and renal clearance were correspondingly reduced. Clinical experience has identified no other significant interactions resulting from administration of other drugs concomitantly with Zovirax Sterile Powder.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Acyclovir was tested in lifetime bioassays in rats and mice at single daily doses of 50, 150 and 450 mg/kg given by gavage. There was no statistically significant difference in the incidence of tumors between treated and control animals, nor did acyclovir appear to shorten the latency of tumors. In 2 *in vitro* cell transformation assays, used to provide preliminary assessment of potential oncogenicity in advance of these more definitive lifetime bioassays in rodents, conflicting results were obtained. Acyclovir was positive at the highest dose used in one system and the resulting morphologically transformed cells formed tumors when inoculated into immunosuppressed, syngeneic, weanling mice. Acyclovir was negative in another transformation system.

No chromosome damage was observed at maximum tolerated parenteral doses of 100 mg/kg acyclovir in rats or Chinese hamsters; higher doses of 500 and 1000 mg/kg were clastogenic in Chinese hamsters. In addition, no activity was found in a dominant lethal study in mice. In 9 of 11 microbial and mammalian cell assays, no evidence of mutagenicity was observed. In 2 mammalian cell assays (human lymphocytes and L5178Y mouse lymphoma cells *in vitro*), positive responses for mutagenicity and chromosomal damage occurred, but only at concentrations at least 25 times the acyclovir plasma levels achieved in man.

Acyclovir does not impair fertility or reproduction in mice at oral doses up to 450 mg/kg/day. In female rabbits treated subcutaneously with acyclovir subsequent to mating, there was a statistically significant decrease in implantation efficiency but no concomitant decrease in litter size at a dose of 50 mg/kg/day.

Pregnancy: Teratogenic Effects. Pregnancy Category C. Acyclovir was not teratogenic in the mouse (450 mg/kg/day, p.o.), rabbit (50 mg/kg/day, s.c.) or rat (50 mg/kg/day, s.c.).

Although maximum tolerated doses were tested in teratology studies, the plasma levels obtained did not exaggerate maximum plasma levels that might occur with clinical use of intravenous acyclovir.

There have been no adequate and well-controlled studies in pregnant women. Acyclovir should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when Zovirax is administered to a nursing woman.

ADVERSE REACTIONS: The most frequent adverse reactions reported during controlled clinical trials of Zovirax in 64 patients were inflammation or phlebitis at the injection site following infiltration of the I.V. fluid in 9 (14.0%), transient elevations of serum creatinine in 3 (4.7%), and rash or hives in 3 (4.7%). Less frequent adverse reactions were diaphoresis, hematuria, hypotension, headache and nausea, each of which occurred in 1 patient (1.6%). Of the 63 patients receiving placebo, 3 (4.8%) experienced inflammation/phlebitis and 3 (4.8%) experienced rash or itching. Hematuria and nausea were experienced by placebo recipients at the same frequency.

Among 51 immunocompromised patients, one, a bone marrow transplant recipient with pneumonitis, developed seizures, cerebral edema, coma and expired with changes consistent with cerebral anoxia on postmortem biopsy; another immunocompromised patient exhibited coarse tremor and clonus.

Additional adverse reactions were reported in uncontrolled trials. The most frequent adverse reaction was elevated serum creatinine. This occurred in 9.8 percent of patients, usually following rapid (less than 10 minutes) intravenous infusion. Less frequent adverse experiences were thrombocytosis and jitters, each in 0.4% of patients.

Approximately 1% of patients receiving intravenous acyclovir have manifested encephalopathic changes characterized by either lethargy, obtundation, tremors, confusion, hallucinations, agitation, seizures or coma (see PRECAUTIONS).

OVERDOSAGE: Overdosage has been reported following administration of bolus injections, or inappropriately high doses, and in patients whose fluid and electrolyte balance was not properly monitored. This has resulted in elevations in BUN, serum creatinine and subsequent renal failure.

Precipitation of acyclovir in renal tubules may occur when the solubility (2.5 mg/ml) in the intratubular fluid is exceeded (see PRECAUTIONS). A six hour hemodialysis results in a 60% decrease in plasma acyclovir concentration. Data concerning peritoneal dialysis are incomplete but indicate that this method may be significantly less efficient in removing acyclovir from the blood. In the event of acute renal failure and anuria, the patient may benefit from hemodialysis until renal function is restored (see DOSAGE AND ADMINISTRATION).

DOSAGE AND ADMINISTRATION: CAUTION — RAPID OR BOLUS INTRAVENOUS AND INTRAMUSCULAR OR SUBCUTANEOUS INJECTION MUST BE AVOIDED.

Dosage: ***MUCOSAL AND CUTANEOUS HERPES SIMPLEX (HSV-1 and HSV-2) INFECTIONS IN IMMUNOCOMPROMISED PATIENTS*** — 5 mg/kg infused at a constant rate over 1 hour, every 8 hours (15 mg/kg/day) for 7 days in adult patients with normal renal function. In children under 12 years of age, more accurate dosing can be attained by infusing 250 mg/M^2 at a constant rate over 1 hour, every 8 hours (750 mg/M^2/day) for 7 days.

SEVERE INITIAL CLINICAL EPISODES OF HERPES GENITALIS — The same dose given above — administered for 5 days.

Therapy should be initiated as early as possible following onset of signs and symptoms.

PATIENTS WITH ACUTE OR CHRONIC RENAL IMPAIRMENT: Refer to DOSAGE AND ADMINISTRATION section for recommended doses, and adjust the dosing interval as indicated in the table below.

Creatinine Clearance (ml/min/1.73M^2)	Dose (mg/kg)	Dosing Interval (hours)
>50	5	8
25-50	5	12
10-25	5	24
0-10	2.5	24

Hemodialysis: For patients who require dialysis, the mean plasma half-life of acyclovir during hemodialysis is approximately 5 hours. This results in a 60% decrease in plasma concentrations following a 6 hour dialysis period. Therefore, the patient's dosing schedule should be adjusted so that a dose is administered after each dialysis.

Method of Preparation: Each 10 ml vial contains acyclovir sodium equivalent to 500 mg of acyclovir. The contents of the vial should be dissolved in 10 ml of sterile water for injection or bacteriostatic water for injection containing benzyl alcohol yielding a final concentration of 50 mg/ml of acyclovir (pH approximately 11). Shake the vial well to assure complete dissolution before measuring and transferring each individual dose. DO NOT USE BACTERIOSTATIC WATER FOR INJECTION CONTAINING PARABENS. It is incompatible with Zovirax Sterile Powder and may cause precipitation.

COOLEY'S ANEMIA FOUNDATION, INC. RESEARCH FELLOWSHIPS

The Cooley's Anemia Foundation, Inc., invites applications for fellowships to both postdoctoral fellows and junior faculty members interested in the field of Cooley's anemia with stipends of up to $15,000. The deadline for receipt of applications is May 1, 1986. Awards will be made by June 15, 1986, and funding will begin July 1, 1986, for one year with the possibility of renewal for a second year.

For application forms and further information write:
Mr. Michael C. DiFilippo, National Executive Director, Cooley's Anemia Foundation, Inc., 105 East 22nd Street, Suite 911, New York, New York 10010. Telephone: (212) 598-0911.

DIRECTOR COMPREHENSIVE SICKLE CELL CENTER

The Children's Hospital Medical Center and the University of Cincinnati College of Medicine are seeking a Director for the Comprehensive Sickle Cell Center. Candidates must have either a MD or PhD with experience in an area of medicine of importance to patients with sickle cell disease. The Director may have background in a variety of disciplines including physiology, pharmacology, rheology, cardiology, hematology, pathology or another area of importance to sickle cell disease. The experience should also include writing and receiving grants from granting agencies and management of departmental personnel. Responsibilities will include research having direct significance to sickle cell disease or research which may eventually lead to an understanding of the pathogenesis or treatment of patients with this disease. Please reply with curriculum vitae to: Beatrice Lampkin, MD, Hematology/Oncology Division, CHILDREN'S HOSPITAL MEDICAL CENTER, Elland & Bethesda Avenues, Cincinnati, OH 45229. (513) 559-4266. An Equal Opportunity Employer M/F.

Advances in Haematology 1986

9–13 June 1986

This is a five-day course for specialists and trainees in haematology, with emphasis on progress in the fundamental basis of blood disorders, their diagnosis and their treatment.

Topics include: Haemopoietic cell cultures; Blood cell genes newly cloned; Immune and auto-immune disorders; Bone marrow transplant; Biology and therapy of acute leukaemias; New diagnostic methods in haematology.

There will be lectures, clinical case presentations, a clinico-pathological conference and diagnostic slide sessions. Speakers will be members of the Department of Haematology and the MRC Leukaemia Unit (D. Catovsky, E.C. Gordon-Smith, J. Hows, S.M. Lewis and L. Luzzatto) as well as eminent guest lecturers.

Course Organisers: Drs. S.M. Lewis and J.M. Goldman.

Course fee (including catering): £200.

Application forms from: School Office (SSC), Royal Postgraduate Medical School, Hammersmith Hospital, Du Cane Road, London W12 0HS, Tel: 01-743 2030 ext 2242.

THE CHOICE IS YOURS

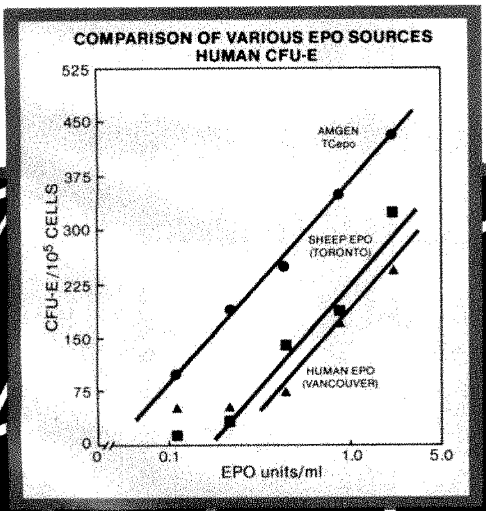
TCepo

Human recombinant erythropoietin for tissue culture, where quality is not compromised for price!

Compare for yourself! You'll find:

- Highest Product Performance
- Consistency Lot-to-lot
- No Inhibitory or Toxic Effects
- Best Price / Quality Value

Unit for unit your research dollar goes farther with TCepo!



CFU-E and BFU-E

Ultrapure EPO

Human recombinant erythropoietin for research applications requiring a homogeneously purified preparation.

- Highest Available Purity (>95%)
- Unparalleled Specific Activity (>70,000 U/mg)
- Protein Free Formulation

AMGen BIOLOGICALS

The New Standard for Lymphocyte Separations

NEW LARGER 16mm SIZE!

LeucoPREP™ makes "Ficoll-Hypaque" a thing of the past

Now you can prepare peripheral blood samples for immunofluorescence staining and analysis four times faster and for much less cost—with LeucoPREP, the new cell separation tube from Becton Dickinson Immunocytometry Systems.

Two easy steps to success

Save time... Save money...

1) Pipette anticoagulated whole blood into a LeucoPREP Tube
2) Centrifuge at room temperature

There's no dilution required—and no extra set-up time.

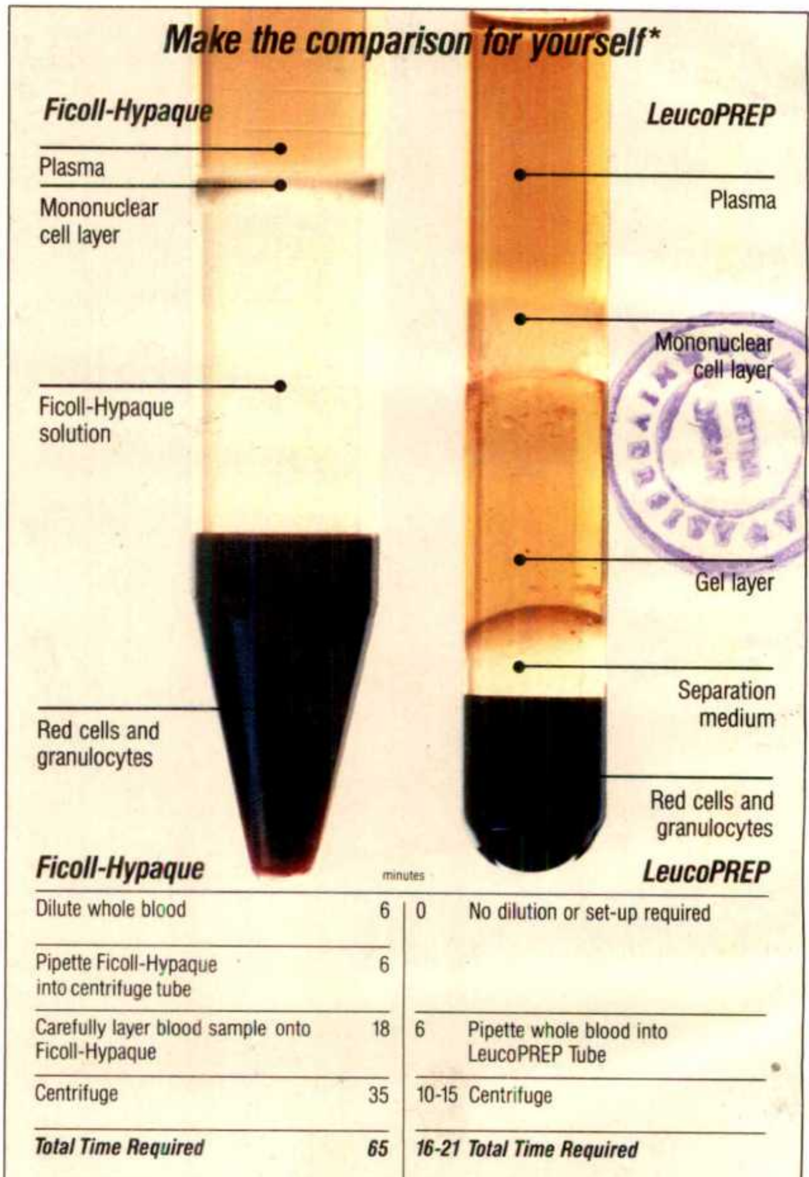
Choose the size that fits your application

LeucoPREP Cell Separation Tubes are now available in two convenient sizes: 16mm (10ml) and 13mm (3ml). Both sizes feature a sterile interior for subsequent functional studies.

Find out how easy and inexpensive cell separations can be

For a free sample of LeucoPREP Tubes, contact your Becton Dickinson Immunocytometry Systems representative. You'll never have to do Ficoll-Hypaque preps again.

Make the comparison for yourself*



Ficoll-Hypaque	minutes		*LeucoPREP*
Dilute whole blood	6	0	No dilution or set-up required
Pipette Ficoll-Hypaque into centrifuge tube	6		
Carefully layer blood sample onto Ficoll-Hypaque	18	6	Pipette whole blood into LeucoPREP Tube
Centrifuge	35	10-15	Centrifuge
Total Time Required	***65***	***16-21***	***Total Time Required***

Total Labor Savings with LeucoPREP—44 to 49 minutes!

**Comparison based on preparation of six samples. There is no significant difference in yield or purity between the two methods. Data available on request.*

Sterile interior. For *in vitro* diagnostic use. Not intended for blood collection.
